Terne metal is more expensive than zinc, but much cheaper than tin. Its advantage lies in the fact that it has certain of the properties of tin at a much lower cost. Under alternating exposure to air, it will remain bright where zinc will form oxides and carbonates. Therefore, terne plate is used for gasoline tanks, where any products of oxidation might clog the fuel line. The surface of terne plate is soft and has a greasy feel. The metal will not flake off, is very ductile, and seems to have considerable lubricating value. Thus, terne plate is used for deep drawing operations where a corrosion resistant material is desired. Its bright attractive finish makes it well suited to articles where appearance and corrosion resistance are both necessary, such as in burial caskets. A further advantage lies in the fact that it can be painted without weathering, which makes it an ideal roofing material.

Miscellaneous Hot Tinning—Wire and narrow strip are hot tinned continuously. The excess tin is removed by running the wire or strip through a wiping fixture, similar to a die, which is packed with asbestos or charcoal. This gives a thin coating, usually amounting to less than 0.00005 in. in thickness or about 0.025-0.035 oz. per sq. ft. of single surface. (With strip this weight would be doubled to give weight per sq. ft. of material, or the equivalent of 0.6-0.9 lb. per base box of tin plate.) For heavier coatings, other means of wiping, such as steam jets, compressed air, and a strong counter current flow of palm oil, have been suggested and used to a limited extent.

Preparation of wire and strip consists essentially of cleaning or pickling and passage through a zinc chloride flux before entering the pure tin bath. Since no palm oil is used the surface of the tin bath should be covered with charcoal to avoid oxidation. Strip tinned continuously in this way seldom exceeds 6 in. in width at present.

Fabricated articles are degreased before tinning by vapor cleaning or other suitable methods. This is followed by pickling in hot dilute sulphuric acid, temporary storage in dilute hydrochloric acid, as in making tin plate, fluxing and tinning.

Zinc chloride or zinc chloride containing a slight amount of ammonium chloride is a positive flux which is widely used in tinning fabricated articles. Molten tallow is sometimes used for fluxing. Usually the products to be tinned are first immersed in a preliminary tinning bath, then immersed in a second tinning pot to secure a better coating. In this way much of the iron-tin dross that forms remains in the first pot and the second pot can be maintained with a purer tin bath. The articles may be brushed or wiped while the tin coating is still fluid to assure complete coverage, then redipped momentarily to leave a free, smooth surface. As a final finishing operation, the articles are either withdrawn through a palm oil or molten tallow division of the final tinning pot or dipped in a separate bath of such material to permit drainage of the tin coating. The amount of tin adhering depends, of course, largely upon the temperature of this finishing bath and the time permitted for drainage, but the coating is always heavy compared to standard coke tin plate. A finishing touch is usually given by dipping the edge or bottom portion of the article, to which excess tin has drained, into a hot tin bath to remove the heavy tin concentration at this point. Cloth, bran, or sawdust may be used for the final polishing and grease removal.

Cast iron parts are not readily tinned due to the graphite in the iron and the difficulty in pickling to give a clean surface. Where possible, sand blasting or other mechanical means to effectively remove the casting skin is best. This is followed by pickling in warm sulphuric acid (5 or 6%) containing an inhibitor, storage in dilute hydrochloric acid, fluxing in zinc chloride containing up to 35% ammonium chloride and tinning in the general manner described for fabricated articles. Frequently a cold 5% hydrofluoric acid pickle is needed to remove residual sand. Surface decarburization does not always help in making the casting more easily tinned but an intermediate layer of pure iron, copper, or nickel which may be plated on electrolytically or by replacement is an advantage.

Retinning—Retinning used parts is fundamentally a repetition of primary tinning except that more attention must be paid to mechanical cleaning or to pickling the spots that have become rusted. For local repairs on large sections it is frequently much easier to clean mechanically and metal spray with tin than to dismantle and retin. By following normal soldering procedure prefaced by thorough

cleaning, and using pure tin in place of solder, it is often practical to repair small defects in place without the necessity for retinning the whole article.

Zinc Coatings

By W. M. Peirce*

Zinc coating, or galvanizing, as it is commonly termed, is an old method of protecting iron and steel against corrosion. It is applied to a greater tonnage of steel products than any other metallic coating method and provides the most economical protection for the broad field where it is properly applicable. The major established applications of zinc coating on steel products are: Roofing and siding sheets, wire and wire products for all outdoor exposure, hardware for outdoor use, pipe and conduit, and exposed structural steel. In short, wherever steel is exposed to atmospheric corrosion, zinc coating is a standard and effective method of protection.

The effectiveness of zinc coatings depends, first on the relatively slow rate of corrosion of zinc as compared with iron and the much less objectionable appearance of the white, nonstaining corrosion products of zinc as compared to iron rust, and second, to the electrolytic protection afforded to iron by zinc. The latter factor prevents corrosion of the iron from occurring at minor discontinuities in the zinc coating such as sheared edges of sheets, cut ends of wire or abrasions in the surface. This electrolytic or "sacrificial" protection extends away from the zinc coating over exposed iron surfaces for a distance of as much as $\frac{1}{4}$ in. The distance varies with the properties of the moisture film as an electrolyte, being a maximum under such conditions as the presence of salt water.

Zinc coatings yield the longest life under rural exposure conditions where the air is free from sulphur gases and other industrial fumes. They give very satisfactory results in salt air exposures. They are most rapidly attacked in highly acid industrial atmospheres but are nevertheless widely used in such atmospheres. Frequently the combination of a zinc coating and an acid resisting paint or other organic coating is most effective, the zinc forming a better base for the organic coating and preventing its rapid failure by undercutting corrosion when the organic coating is penetrated.

When zinc coatings are to be painted for decoration or protection it is desirable to use a suitable primer such as a zinc dust primer which does not lose adherence on aging. The adherence of ordinary paints is improved by weathering of the zinc surface or by etching it chemically. Phosphate treated galvanized sheets are also on the market to which ordinary paint adheres well.

Zinc coatings are occasionally subject to an abnormal type of corrosion resulting in bulky white corrosion products. This originates from contact with water without free access of air. Galvanized sheets should be stacked on edge rather than flat to prevent rain or condensed moisture from being held between the sheets which may cause this type of corrosion. Zinc coated material which is to be used where "sweating" or other exposure to stagnant water may occur can be protected by a chromate surface treatment which has been developed for this purpose.

Since under the exposure conditions where zinc coatings are used, zinc has an appreciable rate of corrosion and since the coatings which can be readily applied are measured in one or two thousandths of an inch or less, it is obvious that the life of the coating will not be indefinite but will be determined by the thickness of the coating. Many comprehensive researches have shown that all other factors such as the method of applying the zinc coating, the purity of the zinc, and the degree to which it is alloyed with the iron are minor in determining life as compared to the thickness of the coating.

Zinc coatings are measured in ounces per sq.ft. of surface for all products except sheet. In the case of sheet, the weight of coating is stated in terms of ounces per sq.ft. of sheet which, since the sheet is coated on both sides, is twice the average weight of coating per sq.ft. of surface. The terms "Regular", "Tight Coat", and "Extra Tight Coat" as used in the trade refer to relative freedom from visible flaking of the coating when bent. Since this tightness of the coating to the base is ordinarily achieved by reducing the weight of coating, the terms have come to connote varying weights of coating—the "extra tight coat" corresponding to the thinnest coating. Weights of coating for many classes of galvanized products have been specified by the A.S.T.M. and are given in Table I. For a description of the methods of properly measuring the thickness of coating (which varies in uniformity

*Chief, Research Division, The New Jersey Zinc Co., Palmerton, Pa. Prepared for the Subcommittee on Metallic Coatings; H. S. Rawdon, General Chairman.

to a degree dependent on the method of application), the A.S.T.M. specifications should be consulted.

Table I
Nominal Weights of Coating for Sheet*
As given in A.S.T.M. Specifications

^bWeight of coating in ounces per sq.ft. of surface.

Table I should not be construed as representing the maximum weight of coating desirable for every application nor the maximum obtainable.

Zinc coatings are commercially applied by four methods. The oldest and most widely used is hot dipping. In this process the steel is first pickled in sulphuric or hydrochloric acid to remove all scale then washed to remove iron salts and finely divided iron. To be completely effective, this must be combined with scrubbing. Any iron salts or finely divided iron left on the surface form dross in the galvanizing pot. The work is next "fluxed" in weak hydrochloric acid or in a strong zinc chloride solution, partially dried and introduced into a bath of molten zinc. Fluxes, usually ammonium zinc chloride mixtures, and various mechanical devices are used to keep the surface of the zinc bath clean at the points of entry and exit. These vary, of course, with the type of material being handled. Sheets are fed by driven rolls immersed in the bath and exit between partially submerged spirally grooved rolls. Wire is pulled through guides and exits through sand, charcoal or a wad of asbestos mechanically held in contact with it. These exit rolls and "wipes" smooth the surface and remove some of the zinc. Other products than sheet and wire are handled semimechanically or by hand and may be shaken, jarred, rotated, or centrifuged (as in the case of nails and small parts), to evenly distribute the coating and remove excess zinc. In all cases the work must be properly handled until the coating has frozen in order to avoid marking and to secure as even a distribution as possible. The appearance may be controlled by the use of cooling air, the application of SO₂ or ammonium chloride to the still molten coating and by local chilling to start crystallization and control spangle pattern.

Variations to every step described above have been proposed and many are in use. For example, cleaning may be accomplished by oxidation and reduction of the surface. Fluxes can be eliminated if the material, its surface free from oxide, is introduced through an inert or reducing atmosphere. The character of the alloy layers (see below) and of the coating may be varied by varying the composition of the steel surface through carburizing, phosphorizing, and other surface treatments, or through the addition of alloying elements to the zinc bath.

In the hot dip method the zinc alloys with the iron forming one or sometimes two layers of definite iron-zinc alloys between the steel base and the outer layer of substantially pure zinc. The character and thickness of these alloys are dependent on many factors in the process: The temperature of the zinc bath, the time of immersion, the composition of the steel, the condition of the surface. The adherence of the coating when bent is affected by the alloy layers, a thin, even alloy layer being most desirable.

Hot dip coatings consisting entirely of iron-zinc alloys are produced on sheet and wire either by very tight "wiping" of the work (see below) or by subsequent heat treatment which causes all of the zinc to alloy with the iron. Such coatings when bent, crack in an infinite number of very fine cracks with some dusting of the coating. The resulting appearance of the bend is more desirable than the flaking which sometimes occurs when ordinary heavy coatings are bent but unless the flaking is very severe the life remains proportional to the thickness of the original coating, regardless of flaking or bending, because of the electrolytic nature of the protection.

The purity of the zinc used in hot galvanizing has an effect on the bending properties of the coatings. Of the common impurities found in zinc, cadmium alone seems to be important. Its presence adversely affects the bending properties of the coatings by embrittling the outer layer of zinc. Aside from this effect, the grade of zinc used has no known effect on the properties of the coating. Difficulties are encountered with most methods of sheet galvanizing when using high purity zinc and for this, as well as economic reasons, nearly all sheet galvanizing is done with "Prime Western" and other of the less pure grades of zinc. High purity zinc is used in producing high quality galvanized wire where the coating must be heavy and must not flake when bent in a splice.

Tin, to the extent of 1 or 2%, is frequently added in sheet and hardware galvanizing to control the spangle, that is, the crystalline appearance of the surface. Aluminum is also added in very small fractions of a per cent in "hand dip" galvanizing (other than sheet and wire) to improve brightness.

The thickness of the coating applied by hot dipping depends on the time of immersion (which controls the thickness of alloy), the speed of withdrawal from the bath (which controls the amount of zinc adhering) the temperature of the bath (which affects both), and on the amount of zinc removed by wiping, jarring, or centrifuging. In the case of sheets the depth of metal above the line of contact of the exit rolls is an important factor. In general, it may be stated that heavy coatings may be more cheaply applied by hot dipping than by any other method but that their adherence when bent may be inferior to electrodeposited coatings.

The electrogalvanizing method of zinc coating is simply a zinc electroplating process. In the past, thin dull coatings have been produced at low rates of deposition. Modern practice has departed from this in two major directions: One, the rapid application of heavy coatings and two, the production of relatively thin decorative coatings of high luster and brightness.

In both cases, as in other electroplating operations, cleaning of the surface is of major importance and a considerable part of modern development in the art, particularly in the field of rapid deposition, relates to cleaning. Parts supplied for bright zinc plating normally carry only a film of grease and drawing lubricant which is removed by cathodic treatment in an alkaline solution. Flat and round steel wire furnished for rapid, high current density plating frequently carries a film of rust which when removed by suitable acid treatment leaves a film of undissolved or redeposited material which must be removed prior to plating. An alternative method involving electrolytic treatment in molten caustic soda has been used commercially.

Rapid electrodeposition is attained by the use of high current densities (of the order of 200-500 amperes per sq.ft.) and pure electrolytes. The electrolyte may be a simple highly acidulated (sulphuric acid) solution of zinc sulphate or a less highly acid zinc sulphate solution containing secret addition agents to promote brighter and smoother deposits.

The replenishment of the zinc in this process is accomplished by one of two means. In one case zinc ore is leached with sulphuric acid to abstract the zinc. The resulting solution is too impure for high current density electrolysis and requires removal of the impurities prior to use. Insoluble anodes (usually of a lead alloy) are used in the electrolysis. In the less highly acid solutions zinc is supplied directly in the form of anodes of high purity zinc which are readily available. Each method has its own advantages but relatively little data on comparative costs are available.

Solutions for applying bright lustrous deposits are of the alkaline cyanide type containing various organic and inorganic ingredients to promote brightness. In one case brightness and high luster are obtained solely by maintaining the electrolyte in a state of very high purity. In all cases the zinc content is supplied by means of zinc anodes. It is a general impression in the industry that zinc of high purity is required for best results.

Electrogalvanizing is not being applied to sheet on any extensive commercial scale as yet. Electrogalvanized coatings consist of a single layer of zinc without any alloy layer. As a result, they are very adherent when bent regardless of thickness unless the cleaning has been carried out imperfectly. Electrogalvanizing offers the advantage, important in many cases, of involving no heating of the steel. Also it is claimed that greater uniformity of coating can be obtained in the case of wire but with many or most products to be galvanized this advantage cannot be expected. The appearance of electrogalvanized coatings is considered preferable in some uses. The practical range of coating thickness obtainable by electrogalvanizing is greater than by hot dipping but little information on relative costs of comparable weights of coating applied by the two methods is available.

Sherardizing which is described elsewhere in this Handbook is a third method of zinc coating which produces very uniformly distributed coatings consisting entirely of iron-zinc alloy.

Spray coating, also described elsewhere in this Handbook, should be mentioned here since it affords a means by which parts too large for treatment by any of the other methods, may be zinc coated. Like electrogalvanizing, it involves no heating of the steel.

Sprayed Metal Coatings

By R. M. Burns*

Any metal which is fusible in the oxyacetylene or oxyhydrogen flame may be sprayed. The process is particularly suitable for coating large structures, such as storage tanks, towers, dock gates, tank cars, and water turbines; it is also useful for coating articles which because of shape or accessibility are not readily coated by other methods as, for example, cooling coils, refrigerating and ventilating equipment. In the decorative field, aluminum, bronze and other metals are applied to elevator grills, castings, light posts and other miscellaneous articles of manufacture. In maintenance and repair shops metal spraying is rather widely employed to rebuild worn parts such as crankshaft bearings, camshafts, armature shafts, pistons and cylinders.

The metal spraying process is usually known as the Schoop process after the name of its inventor, M. U. Schoop, who first developed it on a commercial basis about 1910. Essentially the process consists in melting the metal which is to be deposited, atomizing the molten metal by means of an air blast, and depositing the atomized metal upon the surface to be coated. In its original development the equipment consisted in a reservoir of molten metal which together with the auxiliary parts weighed a ton. Commercial success of the process begins, however, with the development of the portable "pistol" type of equipment weighing about four pounds. In this equipment the metal to be deposited is used in the form of powder or wire. A modern process for using liquid metal has been developed to accommodate four pounds of metal previously melted in a gas heated crucible. The pistol in this case is rather heavy and the process, although limited to low melting metals, is said to be rapid in operation and to produce coatings of uniform character.¹

The powder process of metal spraying consists in heating finely divided metallic powder to its melting point by blowing it through the flame of a blow pipe and projecting the resulting spray by an air blast. The process is limited commercially to metals of low melting point and in particular to zinc which can be obtained in powder form at a reasonable cost.

The method of metal spraying of principal importance is that in which metal in the form of wire is used in a gas fired pistol. In this process, the wire is advanced into the nozzle of the pistol at a constant rate by means of an air driven turbine, the end of the wire being melted and atomized continuously as it reaches the inner part of the conical flame. The size of the wire employed depends upon the metal to be sprayed and the character of deposit which is desired. In general, wires 0.125 in. in dia. may be used for heavy duty spraying, while for ordinary deposits wires from 0.08-0.03 in. in dia. are commonly used.

In its simplest form the nozzle of the gas fired pistol consists of three concentric tubes. The wire is advanced through the central tube, the gaseous mixture through the annular space surrounding this tube while the compressed air which accomplishes the atomizing and spraying passes through the outermost annular space or tube. The gaseous mixture of either hydrogen or acetylene and oxygen is used at pressures of 15 psi., and the most suitable air pressure is 50-60 psi.

For the spray coating of small parts a number of mass coating machines have been devised. Usually these are rotating drums, into the ends of which spray guns are mounted.

The efficiency of deposition of sprayed metal coatings depends upon the process employed, the metal used and the distance of the nozzle from the surface being sprayed. For the wire pistol and the nozzle from 4-8 in. away the efficiencies of deposition are as follows: aluminum 90-85%, brass 80-75%, zinc and tin 73-87% and lead 65-60%, respectively.

An electric metal spraying would seem to have some advantages, especially with respect to portability. Much study has been devoted to this aspect of metal spraying and the practicability of the method has been demonstrated. However, the method is not used commercially as yet.

Nature and Properties of Sprayed Metal Coatings—The minute semimolten particles which comprise the spray acquire a superficial oxide coating which becomes incorporated in the coating. The particles of metal upon impinging upon the base

*Asst. Chemical Director, Bell Telephone Laboratories, New York.

Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

metal are flattened into relatively thin scales which are rapidly chilled by the passing air blast. As the coating is built up these scales become interlocked with others preceding and following them, giving rise to a structure of rather high intrinsic tenacity. There are, however, cavities of microscopic size between the scales at numerous points with the result that the coating is somewhat porous in nature. These cavities, together with small amounts of oxide, have the effect of reducing the density of sprayed metals. In the following table there is given a comparison of the values of density obtained for sprayed metals with the accepted values for the same metals in the ordinary form.

	Density in Cast Form	Density of Sprayed Metal
Aluminum.....	2.70	2.31
Zinc.....	7.14	6.32
Tin.....	7.31	6.82
Copper.....	8.92	7.51
Lead.....	11.34	9.77
Brass.....	8.30	7.32
Bronze.....	8.76	7.77

The density of sprayed metals may be increased by working or by heat treatment. The presence of pores in sprayed coatings is not particularly objectionable in the use of metals such as zinc, the pores of which upon exposure to moist air become filled with corrosion products, thereby improving the continuity of coating. More recently² the application of varnish to sprayed nickel coatings has been advocated as a method of reducing porosity. Usually, however, coatings are applied of sufficient thickness to prevent the existence of pores which extend through the entire coating. In some cases an undercoating of another metal, as for example zinc under tin, is used to provide a thicker protective coating. In the use of sprayed metals on bearing surfaces porosity is of some advantage in absorbing lubricants and maintaining in this way an oil film, the presence of which reduces wear.

The particles of sprayed coatings are slightly work hardened and this together with the presence of oxide results in a hardness somewhat in excess of that of the same metal in the cast form. A comparison of the scratch hardness of sprayed and cast metal is as follows:

	Width of Scratch in Cast	Millimeters Sprayed Coat
Tin.....	0.08	0.056
Aluminum.....	0.06	0.044
Zinc.....	0.05	0.032
Copper.....	0.05	0.029
Brass.....	0.05	0.032
Bronze.....	0.023	0.025

The adherence of sprayed coatings to the base metal is generally of a lower order of magnitude than that obtained in other methods of application. In the absence of alloying or chemical action between the coating metal and base material it becomes essential that the surface of the latter be clean and roughened. The best results are obtained with freshly sand blasted surfaces for this treatment appears to provide angular indentations and recesses to which the sprayed coating may become anchored. Angular steel grit may be used in place of sand for the surface blasting operation. Where it is feasible to preheat the surface to be coated it is said to give improved adherence.³ This is accomplished in some designs of pistol by the attachment of gas jets. In the coating of small articles in drums it is not difficult to preheat the parts beforehand in an adjacent chamber.⁴

Protection Afforded by Sprayed Metal Coatings—In the protection of ferrous metals against corrosion, coatings of sprayed metals of somewhat greater thickness than those applied by hot dipping and electroplating methods are required to assure comparable service. It is common practice, for example, to use sprayed zinc and aluminum coatings 0.004-0.012 in. in thickness depending upon the severity of the exposure. For tin, lead and nickel coatings, metals which do not protect iron electrochemically, coating thicknesses of 0.010-0.025 in. are used. Iron and steel parts which are to be exposed to high temperatures, such as grate fingers, stacks and certain sections of the superstructures of boats are sometimes protected with sprayed aluminum coatings. In these cases from 0.006-0.010 in. of aluminum is used.

Reclamation of Worn or Undersized Parts by Metal Spraying—One of the most attractive applications, and now probably the largest field of usefulness, of metal

spraying is in building up the worn bearing surfaces of large machines.¹ Shafts of all sorts, cylinders, valves, piston rods, rolls, and axles may be readily reclaimed at a fraction of their original cost by the application of low or high carbon steels, stainless steels, or of nonferrous metals and alloys, such as copper, nickel, bronzes, brasses and Monel metal. The most common method of applying sprayed metal to such parts is as follows:

The worn shaft is mounted usually on a lathe or rolls in order to facilitate its rotation. The surface of the shaft is prepared for spraying by first undercutting to clean up the worn areas then blasting with sand or steel grit which roughens the surface in order to secure adequate adhesion of the deposited metal. Where heavy coatings are to be applied it is the practice to cut a rough thread in the surface to be coated which may be followed with a mild sand blasting. In the spraying operation the gun may be operated by playing over the surface in the usual manner, or when the shaft can be rotated the gun is mounted in a fixed position and made to traverse the rotating shaft from end to end. Thus a deposit of uniform thickness greater than the finished size by perhaps $\frac{1}{8}$ in. is obtained over length of the shaft. Finally, the oversized shaft is ground down to the proper dimension by lathe finishing or by means of wet emery and polished with fine emery. In a similar fashion large cylinders, such as penstock valve operating cylinders in power houses, have been relined inside.

This process is equally applicable to the building-up of undersized parts, and is often employed for this purpose.

Cost of Metal Spray Coating—The cost of coating ferrous surfaces by metal spraying depends upon the prevailing cost of oxygen, acetylene, compressed air, labor, and metal, besides the cost of surface preparation. Ordinarily the blast cleaning of a plain flat surface will average from 5-10 cents per sq.ft. Based upon an assumed cost of \$2.00 per hour for operation of the spray gun and the metal wire prices prevailing in April 1936, the approximate cost of metal deposition per sq.ft. of surface for coatings 0.005 in. in thickness is as follows:²

Aluminum	\$0.10
Brass23
Cadmium63
Copper20
Lead10
Monel Metal52
Nickel56
Tin24
Zinc10

Coloring Steel

By Dr. C. B. F. Young*

Coloring of Steel in Molten Salt Baths—Molten salt baths produce colors upon iron and steel which have been polished and cleaned, and are effective, but often the temperatures required are too high, so affect the hardness of the metal. Then too, the drag-out effect must be considered. In some types of bath this loss is so great that the bath must be abandoned because of the economic factor.

If sodium hydroxide baths are used, both of the disadvantages mentioned above are avoided as it operates at 300-400°F., and the drag-out is low. The baths should be covered so as to exclude all carbon dioxide, as this unites with the sodium hydroxide to produce sodium carbonate. However, if this is formed, it can be precipitated by the addition of unslaked lime.

A black color is produced in a solution of 400 g. of sodium hydroxide, 10 g. of potassium nitrate and 10 g. of sodium nitrate dissolved in 600 cc. of water. The solution should be used at 250-285°F. The black color appears in 15-30 min. After coloring, the object should be rinsed in hot water, dried, and immersed in hot oil.

Color Produced by Temperature—One of the oldest methods of coloring iron and steel consists of heating the material up to the desired temperature, and holding it there for a definite period. As steel is heated through a gradual range of temperatures, each degree of temperature for a given specimen of steel produces a corresponding shade, which varies from straw yellow, through brown, purple to dark blue. By properly controlling the temperature, each of these colors can be produced.

Below is a table showing the colors with their corresponding temperature. This is only general, as different steels will vary somewhat.

°F.	Color
400	Faint straw
440	Straw
475	Deep straw
520	Bronze
540	Peacock
590	Full blue
640	Light blue

The colors produced by the above method are generally not uniform due to the fluctuation of the temperature. This can be controlled much better provided the steel objects are immersed in a molten bath of lead or salt as described below.

Polished strip steel is colored straw or blue by passing it through a small lead bath at a suitable temperature and speed. The desired color develops after the steel leaves the bath and comes in contact with the air. The amount of coloring is controlled by passing the strip steel through wet waste located a short distance from where the strip emerges from the lead.

Strip steel is also satisfactorily colored by passing it through a salt bath. The coloring takes place in the bath. After leaving the bath the adhering salt must be washed off with hot water and the steel dried before winding it on the reels.

In both methods the strip steel to be colored must be thoroughly cleaned and dried, and free from oil or finger marks.

Sand may also be used as the bath. The sand may be on a hot plate, or better, in a cylinder capable of being slowly rotated and heated by a gas flame underneath. From five to ten minutes will produce a fine rich blue when the sand is at approximately 650°F.

The work may also be placed in a sheet metal box with a small amount of sand. The box and contents are agitated back and forth over a fire.

When using either method, experience will be required to know just when to remove the work from the fire. The sand is sifted out by means of a wire sieve and the work dipped into oil to set the color.

When it is desired to do tinting on a large scale, continuous sand tempering machines are often used. The work is carried through a perforated drum and

*Instructor, Chemical Engineering, Brooklyn Polytechnic Inst., Brooklyn.

heated sand is automatically sifted into the drum. Adjustments of the temperature and rate of feed may be so made that a continuous stream of work having a uniform color is secured.

Heat tinting may also be done on a large scale in a rotary retort without the use of sand. The tint color is controlled by the operator. He must regulate his temperature accurately and keep close watch of the work to be certain that it is removed when the desired color is secured.

For continuous simultaneous heat tinting and tempering, machines are procurable with or without sand as a part of the process. The sand serves to cushion the work to prevent battering which might result in tumbling articles of certain shapes and weights; furthermore, the heated sand insures complete diffusion of the heat throughout the mass of work and therefore greater uniformity in color.

It is important in all heat tinting that sufficient time be allowed for oxidation of the steel at the low temperatures used.

Niter Baths—Steel articles that have been polished and properly cleaned can be given a simple finish by immersing them in molten niter. A mixture of half and half sodium and potassium nitrate is melted in a cast iron or steel melting pot of shape and depth to suit the work. As rust from any sources affects the color of the work, the pot should be cleaned prior to putting in the saltpeter. The niter is melted, superheated to a temperature of about 900°F. and manganese dioxide added in the ratio of about 1 part oxide to 50 parts of niter, by volume. The manganese gives the molten salt a greenish-black tinge, and causes all suspended matter to settle to the bottom of the pot.

The addition of potassium nitrate increases the cost of the process. Potassium salts are deemed necessary when low temperature operation is desired. Potassium salts may be omitted from the bath, however, with equally good results. Sodium nitrate or Chile saltpeter is an excellent bluing medium, although higher operating temperatures are imperative.

As bluing by this process forms an iron oxide film on the work, consumption of the manganese dioxide would be expected. Replacement at the rate of 1 lb. of manganese dioxide every 3 hr. to a 300 lb. batch of saltpeter keeps the bath in condition. While it is doubtful what is the exact function of the manganese dioxide, this much has been observed; that if omitted from the pot the melt does not produce good work. Baths found upon analysis to be charged with iron oxide gave bad results, whereas no excess iron oxide was found in solution in any bath containing an excess of manganese dioxide. (Manganese dioxide has been omitted from some baths with satisfactory results.)

In a niter bath a peacock blue or temper blue can be consistently obtained in the following manner: The articles to be blued are first cleaned and polished. The higher the polish the brighter will be the blue color. A thin coating of oil is then applied and the articles immersed in the hot niter at 600-650°F. The pieces may be suspended individually on wires. Screws, nuts and other small articles may be dipped, inclosed in a wire basket. The parts are held in the niter for a few minutes, and then raised to note the depth of coloring attained. They are then replaced in the molten salt until they reach the desired color. The time required varies with the temperature and with the size of the pieces but is never over 4 or 5 min.

The reaction is nothing more than obtaining a uniformly colored oxide film, as is obtained when tempering steel to color. If left in the niter too long, say 10 min., the film produced is no longer a temper blue or a gun-metal blue, but has become a dirty gray. Preliminary cleaning in gasoline or similar solvent produces a bad finish, resulting in a mottled dirty surface. The oil carried on the surface of the parts takes fire immediately upon immersion in the hot niter, and if any moisture is present on the articles bad spattering of hot salt will occur.

After the right blue is obtained, the articles are quenched in cold, clean water to strike the color, then immersed in boiling water and finally in hot oil. Hot oil dip is necessary in treating small screws or other tiny parts, as it removes from them all moisture, which if left on the blued article will form a spot of red oxide rust, a defect which has a tendency to form at the roots of threads or any reentrant angle. A darker gun-metal blue may be obtained by using a temperature up to 1000°F.

Care should be taken not to dip articles after adding manganese dioxide to a niter bath until the suspended oxide has sunk, as otherwise dirty spots will

appear on the blued article. Cast iron, if highly polished, will take on a gun-metal blue corresponding to that given to polished steel, but it requires about 20 min. immersion at 1000°F. to accomplish this result.

Charcoal Bluing—The charcoal bluing process consists of introducing highly polished work in a bed of hot charcoal. The bed of charcoal is approximately 2 ft. deep. The lower regions of the fuel are in a state of incandescence, whereas the upper layers possess temperatures which are suitable for the development of oxide colors. After the desired shade of blue is developed the work is rubbed vigorously with waste which has been dipped in raw sperm oil.

Oil Blackening—To oil blacken, the polished steel part is packed in a carburizing box, using spent carburizing compound, and properly luted to exclude air. Box and contents are heated to 1200°F., requiring about 1½ hr. At 1200°F. the box may be drawn, the lid opened and the parts riddled free from carburizing compound and at once quenched in oil. A black oxide skin is formed, dull in appearance but uniform in texture.

A comparatively good black color can be obtained quickly by heating the work to a temperature of 1000-1200°F. and quenching into oil. The appearance of this finish depends upon the surface of the work prior to heating. This finish is not so good in color nor in lasting qualities as the gun-metal finish.

Small typewriter parts are given a black finish by heating in a rotary retort furnace to a temperature of about 750°F. After the work has reached the desired temperature, a small quantity (about 1 oz.) of linseed oil or fish oil is added to the charge in the retort. The work is revolved from 3-10 min. longer, when it is taken from the furnace and spread in pans to cool in the air. After cooling the parts are dipped in a rust retarding oil.†

To simultaneously oil blacken and temper, place the articles which have been quenched in oil from the hardening heat and while still covered with the quenching oil, in a rotary drum retort (not perforated). Heat to 500-650°F. and maintain at temperature for the proper tempering time and the finish desired. The longer the time, the deeper and more durable the black color. Allow the retort with its contents to drop below 500°F. before discharging the articles. Then to brighten the black color tumble the articles for a short time in granular cork which is slightly oily.

Gun-Metal Finish—The gun-metal finish, also known as carbonia finish, used on a majority of rifles, shotguns, and revolvers, is in addition used for finishing small parts, such as buttons, screws, pen points, buckles, pins, saw teeth, bicycle chain links, typewriter, and calculating machine parts.

Various types of black finish can be secured. These depend principally upon the finish of the part before the special treatment is given. Cold drawn or highly polished parts will take a glossy black finish. Parts made from ordinary stampings will have a somewhat duller finish, while work which has been sand blasted prior to applying this treatment will have a black matte-like finish.

While not an entirely rust preventative coating, this finish acts as a retardant to the formation of rust.

To apply the gun-metal or carbonia finish, the work is placed loosely in a retort with a small amount of charred bone and heated to 700-800°F. After the articles are thoroughly oxidized the temperature is allowed to drop to about 650°F., when a mixture of bone and 1 or 2 tablespoonfuls of carbonia oil are added. Heating is then continued for a period of several hours. When the work comes from the retort it is a dull grayish-black and by dipping in sperm oil or tumbling in oily cork a uniform black finish is secured.

If the temperatures given will temper too much, a temperature as low as 500°F. can be used, but this lower temperature requires a longer time at heat to color the articles and the color is not so lasting as the color produced at the higher heats.

Gun-metal or carbonia finish may be applied to articles which have first been nitrided, resulting in a pleasing finish resistant to rusting and retaining the surface hardness on the articles, since these coloring temperatures do not temper the nitrided articles.

When a rotary retort is used and when the work is of such a nature that the slow rotation of the retort would cause scratches or in any way mar the finish,

†Fuels and Furnaces, May, 1924, p. 464.

special fixtures may be used to hold the work in place. These fixtures are usually necessary only when large parts are to be finished.

Coslettizing, Parkerizing and Barfing—In Coslettizing, the articles, polished and cleaned, are placed in a solution of ferrous phosphate made from iron filings, about 1% of phosphoric acid and water. The solution is boiled for approximately 2 hr. This treatment yields a light gray coating to steel consisting of basic iron phosphate, which is strongly adhesive. Due to the low temperature used, the physical properties of tempered steel articles are not affected. Even fine springs retain their elasticity and magnets are unaffected.

The method called Parkerizing differs from Coslett's original method by adding an oxidizing agent and catalyzer, usually manganese oxide (MnO), to the 1-2% solution of phosphoric acid which contains ferrous phosphate. The coating produced is then a basic ferrous-ferric phosphate, the ideal coating being one containing 3 of ferrous to 1 of ferric phosphate. After coating, the articles are gray in color, and after drying are usually coated with paraffin oil to give them a deep black color. Considerable variation of color is possible by this treatment. When the articles are first placed in the bath a large quantity of hydrogen gas is liberated, and as soon as this ceases the process is completed.

Barfing renders the metallic surface rather inert by producing a coating consisting of magnetic oxide of iron. This change, reaching to an appreciable depth, gives to the surface the durability of gun-metal. The articles to be treated are cleaned and placed in an air tight oven which has a connection introducing superheated steam at 60-100 psi. When the articles are heated to a dull red heat the steam is introduced. The coating, as one would expect, is resistant to heat. These coatings can be dyed and treated with oil or wax so that their moisture resistance will increase. The natural appearance before sealing is a light bluish slate color which darkens when oil or wax coatings are applied. These coatings incidentally prevent finger marking.

Browning—There are many processes for browning steel. The matter, however, may be summarized by describing one process, in spite of numerous variations, chiefly in the composition of the browning mixture. Other variations occur in manipulation and in the atmospheric conditions, artificial or natural. The longer browning processes have relatively low temperatures and humidities, while the shorter processes have relatively high temperatures and humidities. The longer processes have poor conditions, while the shorter processes have good conditions for rusting.

Procedures in Browning—The articles are first thoroughly cleaned which may be accomplished by boiling for fifteen minutes in a soda solution. Any grease appearing on the surface of such a solution indicates need of soda ash addition. Then dry the parts by placing them on a draining rack. When cooled to approximately 120°F. coat with the browning solution. Apply the browning solution evenly over the surface of the article with a brush, a sponge, or by dipping. Dry for approximately 30 min., apply a second coat of the solution and dry for 30 min. more.

The articles are then placed in a warming room or cabinet, and brought to temperature, which may vary from 140°F. up to as high as 175°F. Dry heat is satisfactory, as it is its function merely to bring the article up to a temperature such that when it is placed in the humid rusting cabinet, dew will not form on the surface, causing spots in the color.

The time in the warming room will naturally vary according to the size of the pieces. Transfer them from the warming room to the rusting room. This must be at the same temperature as that of the warming room (175°F.). Humidity up to the saturation point is desired, but danger of condensation should be avoided, as pitted and spotted work will result if the dew point is reached. Articles are rusted in approximately 1 hr. and 30 min. for such shapes as bayonets, others taking shorter or longer periods, depending on the size and surface.

The rusted metal, now a dirty greenish red, is removed from the humid room to a third cabinet or room, although it is not absolutely necessary. The conditions are the same as the first room. Its object is to set the rust. The rusted metal is allowed to remain in this room for 30 min. Then the article is placed in clean, boiling water for 15 min. The articles are allowed to drain dry, and then are carded on a wire brush or fiber wheel, which removes any loose particles of oxide on the surface. This operation completes the first coating.

After the first coat, three more rustings are applied in substantially the same manner, after which the browned surfaces are given a coating of thin white slushing

All the rooms should have proper thermometer and thermostatic controls, and the rusting room a recording hygrometer. Temperature and moisture should be automatically controlled. The layout of the apparatus should permit a proper flow of work from one process to the other.

The compositions of Browning solutions are given in Table I.

Table I
Compositions of Browning Solutions

Solution	1	2	3	4	5	6	7	8	9	10	11	12	13

Electrolytic Coloring—When iron and steel are covered with an electrolytic coat of another metal or alloy, it is not thought of as coloring but as protecting the base metal. Thus, iron and steel are colored yellow by depositing thereon a brass; red by depositing copper; black by depositing black nickel; and white by depositing a nickel-cobalt alloy. See page 1096 for composition of baths for electrodeposition of metals.

Aside from the deposition of metals and alloys, the deposition of colors by the aid of an electric current is producing good results; examples are as follows:

Blue on Iron—A good blue can be produced on iron by first depositing on this material a thin coating of electrolytic copper, using either the sulphate or cyanide bath. The copper coated steel is then made the cathode in a solution containing 1.25 oz. per gal. cupric acetate and, 0.50 oz. per gal. of gelatin. Pass through this solution a current of 1.5-4.0 amperes per sq.ft., using copper as the anode. After depositing the copper from this solution for about 15-20 min. the cathode is washed in water and immersed for 5 min. in a 5% cupric acetate solution. Hues of startling intensity are produced, one after another in succession, until finally a deep blue develops.

Color Plating—The colors produced have a metallic lustre, are free from dyes or pigments and are light fast. Practically all the colors of the spectrum from violet to red are produced in a single bath. The colors obtained depend on the thickness of the deposit and this in turn depends on the plating time, which may vary from one minute to thirty minutes or more.

The bath is composed of complex organic compounds. The work is made cathode while copper is used as the anode. The current density is approximately 0.5 ampere per sq. ft. with about 0.4 volt.

The finish of the base metal determines its appearance after color plating. Thus an article which is highly polished before color plating has a similar polished appearance after color plating. After the color plating a clear lacquer is applied which increases the resistance of the finish to wear and corrosion.

Molybdate Method—If iron or steel is made the cathode in a bath containing 7-14 oz. per gal. of ammonium molybdate with enough ammonium hydroxide to produce a clear solution, and 1-10 amperes per sq. ft. passed through the cell, various colors and hues can be obtained. The colors change several times in a cycle. When a cycle is complete, the colors are reproduced in a somewhat darker shade. If allowed to continue, black deposits are finally produced, although most of these have the disadvantage of being brittle. This bath, with modifications, can be used for coloring various metals, including aluminum.

Cleaning of Metals

By Dr. Walter R. Meyer*

Introduction—Three general methods for cleaning metals contaminated with oil, grease, or buffing compounds are in use and will be considered separately although the methods may be used individually or in conjunction with one another depending upon the material to be cleaned and the effects desired. Cleaning previous to plating, for example, should be complete, and the work should show no "water break" (on removal from water, the work should be covered by a continuous water film) whereas the requirements for cleaning previous to japanning or enameling are not so rigid. The three types of cleaning which will be considered are as follows: (a) Vapor Degreasing; (b) Emulsifiable Solvent Cleaning; and (c) Aqueous Alkaline Cleaning.

Vapor Degreasing—The vapor degreaser may be likened to the chemist's reflux condenser. A noninflammable solvent, such as trichlorethylene, is heated to boiling electrically or by steam coils in a chamber around the top of which is provided cooling coils or compartments to recondense the hot vapors, preventing the solvent from escaping. The work to be cleaned is hung in the hot vapor which condenses upon the work and washes off the grease and oil. Because the oils removed are only slightly volatile at the operating temperature of the degreaser, the hot vapor will be essentially that of clean solvent although the liquid solvent itself may be badly contaminated. The volume of solvent condensing upon the work to be cleaned and consequently the effectiveness of cleaning, is determined by the weight of the metal, its specific heat, the temperature rise necessary to bring the work to the temperature of the solvent, and the latent heat of condensation of the solvent. For a given metal and cleaner, the amount of vapor condensed will be dependent upon the weight of the metal to be cleaned. It is obvious, therefore, that light metal sections with heavy films of oil will be cleaned poorly, whereas heavy metal with comparatively heavy grease films may be effectively cleaned. The vapor cleaner has the second disadvantage of not being able to completely remove solid dirt from the surface, and frequently the work may be well cleaned of oil, but a cloud of solid dirt may adhere to the work, necessitating a subsequent wiping operation.

To overcome the difficulties mentioned, spray cleaning, combinations of two solvents or a sequence of boiling liquid, cold liquid, and hot vapor may be employed. In the last named sequence, the work is first immersed in the boiling solvent where most of the solid dirt and oil are removed. This cleaner soon becomes contaminated, but the cleaning efficiency of the system is not seriously affected. The work is transferred from the chamber containing the hot solvent to a chamber containing relatively cleaner cold solvent which is formed by the condensation of the vapor from the first cleaner. In this chamber, the work is cleaned of dirt which was not removed in the first chamber, and the solvent in this chamber is kept relatively clean by the constant condensation of the clean hot vapor and the run-off of excess condensate into the first compartment. The work is withdrawn from the cold chamber and held above the hot compartment where the hot clean vapor condenses and removes any residues of oil not removed in the cold chamber. This sequence although requiring more labor for cleaning than the simple vapor cleaning, has proved itself in practice, and allows thin, badly contaminated work to be successfully cleaned.

It is essential in designing vapor degreasers that sufficient heating capacity be provided, otherwise the vapor line in the cleaner will drop too low when the cold work is immersed and the cleaning process will be seriously retarded. Improper height of the vapor column and poor condensing facilities permit large solvent losses and lower the amount of heat which can be applied to the boiling solvent. The equipment should be designed for the required size and volume of work as closely as possible, because too large units allow higher ratios of solvent lost by diffusion to amount of work cleaned, and too small units will permit large solvent losses by displacement of vapor by the work when it is immersed.

Vapor degreasing has several specific advantages: (1) The drying of the work after cleaning is rapid which is of particular value for recessed work or where water stains might be objectionable, and (2) the high temperature of operation

*Managing Editor, Metal Industry, New York.

softens the solid fats and lowers the viscosities of the oils, allowing rapid penetration and removal of material in holes or crevices, (this removal would be difficult with alkaline aqueous cleaners) and, (3) metals such as aluminum or zinc which are attacked by the alkaline cleaners may be cleaned by vapor degreasing with almost no visible effect upon the finish. The installations may be made automatic and are cleaner than alkaline cleaning methods. Vapor degreasing has found particular value for cleaning of metal previous to lacquering, japanning, enameling, and general organic finishing, but must be followed in cleaning previous to plating by an alkaline cleaner to remove traces of organic matter which remain on the surface after degreasing.

The disadvantages of vapor degreasing are (1) increased cost of materials over alkaline cleaning; (2) difficulty in removing solid dirt; (3) toxicity of the solvent (this may be troublesome in poorly designed equipment); and (4) the need for subsequent alkaline cleaning preceding plating operations.

Emulsifiable Solvent Cleaning—The removal of smut from cold rolled steel, and the general removal of solid particles and oil from both ferrous and nonferrous metals has been a difficult problem. The use of emulsifiable solvent cleaners has proved effective in solving cleaning problems of this type. Emulsifiable solvent cleaners are miscible with oils and can be washed off with water although a slight film of oil may remain upon the work and necessitate a subsequent alkaline cleaning treatment before electroplating. The cleaners may be of two general types. One class is composed of a hydrocarbon-soluble emulsifying agent such as sulphonated corn or castor oil, acid sludges, or triethanolamine oleate added to an organic solvent such as high flash naphtha or kerosene. The second class is made by "blending" a soap such as potassium oleate with an organic solvent such as kerosene using such blending or coupling agents as cresylic acid, butyl alcohol, cyclohexanol derivatives, or butyl cellosolve. As much as 10% water may be added to increase the ease of emulsifying.

The use of the solvent cleaner consists in immersing the work to be cleaned in the solvent cleaner where some of the oil is dissolved and each solid particle thoroughly wetted, removing the work, allowing it to drain, and then rinsing in clean running water. A second rinse in clean warm water may follow, after which the work is usually suitable for enameling or japanning. For electroplating, the work is transferred from the running rinse directly into an alkaline cleaner to remove any traces of remaining organic matter. The solvent cleaner can stand considerable contamination from oil and may be used months.

Emulsifiable solvent cleaners are particularly valuable for cleaning chemically active metals such as lead, aluminum, and zinc, since the cleaners are only slightly alkaline and do not attack these metals. The cleaners are nonexplosive and are much safer from a fire hazard standpoint than naphthas or benzine, and they do not have the toxic effects of carbon tetrachloride. However, solvent cleaners will not clean satisfactorily if the work is wet, and the cost of dragout may be prohibitive to their use for work containing wells or pockets.

Alkaline Cleaning—The mechanism of alkaline cleaning, and the composition, testing and application of alkaline cleaners will be considered briefly:

The Mechanism of Alkaline Cleaning—An exact understanding of detergent processes has, as yet, not been realized, but certain factors have been recognized which indicate in various degrees the relative detergent values. These factors are:

1. Wetting of the surface. Good wetting power of an alkaline cleaner is usually accompanied by low interfacial surface tension of the solution.

2. Penetration of the dirt layer. The rate of penetration is greatly influenced by the temperature of the solution and the interfacial surface tension.

3. Emulsification and deflocculation. Without emulsification of the oils and greases, and deflocculation or suspension of the solid dirt in the solution, penetration and wetting power would be of little value.

4. Free rinsing ability. The poor rinsing qualities of certain soaps, such as the stearate soaps, limit their use in commercial cleaning.

5. Saponification. The value of saponification in alkaline cleaning has been overestimated. Vegetable or animal fats, or fatty acids may be removed to some extent by saponification, but the bulk of metals to be cleaned is contaminated with unsaponifiable mineral oils, or insoluble soaps and dirt which cannot be saponified and are removed by the mechanisms of wetting, emulsification and deflocculation.

Composition of Alkaline Cleaners—The usual composition of the older types of cleaners was caustic soda, soda ash, trisodium phosphate and up to 5% rosin or rosin soap. Newly available alkalis and soaps have made possible the formulation

of much more efficient detergents. The first consideration is a source of alkali which is most economically furnished by caustic soda. For milder cleaners, sodium metasilicate or sodium sesquisilicate may be used to advantage. Sodium carbonate or sesquicarbonate and trisodium phosphate are not economical sources of available alkalinity calculated on an equivalent sodium oxide basis.

A constant pH or alkalinity is desired throughout the life of the cleaner and this may be controlled to some measure by the use of substances with buffered alkalinity such as sodium tetraborate, disodium phosphate, or sodium meta, sesqui, or orthosilicate depending upon the pH level desired.

Soaps as sodium resinate, sodium linoleate, or sodium oleate, and soaps from coconut, palm, whale and fish oils are essential parts of a good detergent. Soaps increase the wetting power and are the most valuable aids for emulsification. The choice of soap depends upon the conditions of service. The properties to be considered are: Solubility, optimum cleaning temperature, lather formation, stability, rinsing qualities, hydrolysis, detergent ability and cost. Rosin has been used extensively, for example, because of its low cost, good solubility, nonfoaming tendencies, and ease of rinsing. Sodium stearate, on the other hand, has found little application in alkaline metal cleaners because of its strong lather, low solubility, and poor rinsing qualities. Numerous new synthetic wetting agents have appeared within the last few years, many of which lack the ability to deflocculate and suspend dirt although possessing excellent wetting properties. The high cost of these synthetic wetting agents has limited their application in metal cleaning although they are being used to a greater extent in textile cleaning. Some of these materials are sulphates of higher fatty acids, or naphthalene sulphonated derivatives.

In summary the essential components of a good alkaline metal cleaner are (1) a source of available alkali, (2) a buffer to control the alkalinity, and (3) a soap.

Testing of Alkaline Cleaners—Laboratory test methods for determining the relative cleaning ability of various cleaners have included measurements of surface tension, measurement of the colloidal properties, washing of soiled cloths, measuring the rate of settling of carbon, and the deflocculating action against graphite. These methods are not of sufficient value to determine the relative detergent actions for commercial metal cleaning problems. An excellent beaker test of relative wetting power may be performed by making the cleaners up to the same concentration and temperature, and noting the rate of penetration into the cleaner of steel wool wet with oil. With cleaners of good wetting power, the steel wool may settle within a few seconds whereas with poor wetting power, the steel wool will float upon the surface indefinitely.

When performing factory trials on cleaners, the temperature of operation as well as concentrations must be carefully watched. Too high concentrations may actually clean more poorly than lower concentrations and it may be noted that cleaning ability does not necessarily increase with increased alkalinity. Cleaners with mild alkalies may clean more efficiently than high caustic cleaners. The cleaning trials should be continued for some time since some cleaners maintain an almost constant detergent efficiency whereas others rapidly decrease in cleaning ability because of poor buffering or too stable emulsification of the oil from improper choice of the soap used. The foaming and rinsing qualities should be noted as well as the cleaning ability.

Application of Alkaline Cleaners—For cleaning zinc, aluminum, lead, or tin, the milder alkalies such as metasilicate or trisodium phosphate are used often together with free rinsing soaps. The pH range may be from 8 to 10.5. Light duty and electro-plater cleaners range in pH from 10.5 to 12.5 and heavy duty cleaners vary in pH from 12 to 13.5. Whale or fish oil soap solutions are frequently used as soak solutions either with or without agitation to remove buffing compounds or heavy dirt previous to the use of alkaline cleaners.

Wherever possible, electrolytic cleaning should be used because the gases liberated on the work greatly speed the cleaning action. Soft metals such as lead, zinc or tin must necessarily be cleaned cathodically (object negative electrode) because they would be badly etched if cleaned anodically (object positive electrode). Steel may be cleaned either anodically or cathodically. At the cathode, a greater amount of gas is liberated than at the anode and the hydrogen has some reducing action on oxides present. Some difficulties that may be encountered are hydrogen embrittlement and plating of a smut on the work due to the deposition of iron, copper, and other metals that may accumulate in the cleaner after it is used. Reversal of the

current will not completely remove these smuts but will oxidize metals in the smut so that they will be more readily removed in the acid dip which follows. Anodic cleaning is receiving favor because of absence of embrittlement and smut deposition.

In electrocleaners, the tank should not be used as an electrode, but separate anodes of iron or nickel should be used to prevent attack upon the tank. Chlorides should be carefully avoided and the soap content should be low or else excessive foaming with danger of an explosion, may result. The current densities employed range from 10 to 100 amperes per sq. ft. with the higher current densities giving, obviously, more rapid cleaning action.

Mechanical Methods for Cleaning Metals with Alkaline Solutions

By C. S. Tompkins*

Introduction—This information pertains entirely to the methods of application of alkaline cleaning solutions for the removal of grease and oil from metal surfaces. The chemical content of the solutions and the chemical reactions have been purposely omitted, inasmuch as this is subject matter for another article.

The removal of grease and oil from metal surfaces is in many instances a costly operation, not so much from a standpoint of the chemicals used, as it is from a time and labor cost, therefore, methods of application are as important as the chemicals employed.

Cleaning solutions cannot be standardized in the strict sense of the term because of the different kinds of oils and greases that have been used either to protect the metal or for lubricating purposes.

The strength of the cleaning solution depends upon the hardness of the water in the particular locality, the method of cleaning, the kind of oil and grease to be removed, and the kind of metal to be cleaned; when solutions are used for a particular kind of work and under the same conditions, they can be made standard to accommodate that particular cleaning problem.

Where two or more installations for cleaning metals are available, steel products are usually cleaned in one system and cast iron products in the other, the cleaning solution can then be standard for that particular cleaning problem and system.

When studying the problem of cleaning metal, the following factors must be taken into consideration:

- (1) The nature of the oil or grease to be removed—that is, whether it is animal, vegetable, or mineral. Most animal and vegetable oils or greases saponify readily, while the mineral oils do not.
- (2) The kind of metal to be cleaned—that is, whether or not it will be attacked by an alkali. Brass, zinc, aluminum, and tin are easily attacked by alkalis.
- (3) The standard of cleaning required—whether between operations, before inspection, before assembling, before japanning or enameling, or before electro deposition
- (4) Methods of application of the cleaning solution.

Methods for Cleaning Metals—There are five methods of application for the cleaning solution as follows:

1. Still tank cleaning.
2. Air agitation.
3. Electric cleaning.
4. Steam and alkali spray.
5. Metal parts washing machines.

(1) *Still Tank Cleaning*—Although still tank cleaning, that is cleaning in a tank not equipped with air agitation, is the method most commonly used, it is the most impractical of all the methods. In this method a steel tank is generally used, which is heated either by gas, steam coils, or open steam jets. The temperatures of the cleaning solutions are important; for highest efficiency they should be maintained at or near the boiling point. Because a minimum amount of mechanical action is obtained in still tanks, chemical action is depended upon entirely to saponify or emulsify the grease or oil. In some plants metal, coated with heavy oil and grease which are sometimes in chunks, is put into the cleaning tank. This tends to overload the solution with muck. This objection could be overcome by using two tanks, the first as a soak to remove the heavy grease or oil and the second as the final cleaner, or by hosing off the excess grease and oil before putting the work into the cleaning solution. This is a neglected feature, but is important from the standpoint of cost and uniformity of results.

Heating the Solutions—Steam coils placed on the work side of the tank are most practical. If steam coils are placed on the bottom of the tank, dirt and other foreign substances fall to the bottom of the tank and coat the coils, forming an insulation, so that maximum heat is not obtained. By placing coils on work side of tank, the circulation from the coils will be toward the back of the tank,

*Industrial Department, J. B. Ford Co., Wyandotte, Mich.

which will help to keep the top of the solution free from oil. The area of the coils should be sufficient to keep the solution at or near its boiling point.

(2) *Air Agitation in Solutions*—Open jet steam does not produce a positive agitation. Steam, as it is discharged into the solution, condenses and forms a circulation, while air when discharged into a solution forms bubbles which rise to the top to be released, and in this manner keeps the solution constantly stirred.

Fig. 1 illustrates such an installation for air agitation.

The most practical method of installing air is to have the pipe on the bottom and in the center of the tank and not on the sides. A small pipe with a valve handy for the operator is run down the back of the tank in the center to the bottom, and a straight ell is placed on the opening end, which faces the end of the tank; into this is placed a street ell opening, facing toward the opposite side of the tank (this street ell is used so that the pipe on the bottom of the tank may be raised when cleaning the tank). Into this street ell is placed a straight pipe resting on the bottom of the tank and extending to the center. A tee is attached on the end and a straight pipe extends both ways from the tee on the bottom of tank to the ends. On the ends of these pipes, two pipe caps are attached. Small holes should be drilled on both sides of these pipes to allow air to pass through. To equalize the flow of air into the solution, the holes should be graduated in distance from each other. For instance, if the first hole is 6 in. from the tee, the next holes should be 5½, 5 and 4½ in. This air discharged into the solution forms bubbles and rises to the top creating a positive agitation so that every part of the solution is kept in motion.

As illustrated in Fig. 2, hang over the steam coils a perforated plate to the bottom of which is hinged a false bottom. The cleaning solution in the small space between the perforated plate and the tank heats rapidly, and is expelled through the perforations, attached to which are baffle plates, causing the heated solution to flow upward, forming a complete circle of flow as indicated by arrows in illustration. This method of agitation is not as effective as air agitation, but is nevertheless very efficient and economical.

(3) *Electric Cleaning*—This method of cleaning is accomplished by passing a low voltage (6-12 volts) current through an alkaline solution. An evolution of oxygen is produced at the anode and an evolution of hydrogen at the cathode or work to be cleaned. It has been the custom to make a direct connection of the positive buss rod to the tank and the negative connection to the work rod.

The metal to be cleaned is hung on these work rods, using hooks long enough to allow the metal being cleaned to be immersed in the alkaline solution. It has been found much more efficient, instead of making the direct connection of the positive buss rod to the tank, to make this connection to anode rods and use sheet steel anodes, suspended in the tank. These sheet steel anodes should be nickel plated and as nickel does not deposit in an alkaline solution the anodes will remain perfectly clean at all times. This increases the amperes passing through the solution and materially increases the efficiency of this method.

The results obtained in electric cleaning tanks are uniform and thorough. The evolution of hydrogen produced by the electric current at the cathode or work has an effect of loosening the grease or oil and it is removed very quickly. In some instances the flow of current is reversed, that is, the tank is used as the cathode and the work as the anode. In this case there is an evolution of oxygen at the work. Some tanks are equipped with a double throw switch so that the current may be passed through the solution either way. This is practical,

Fig. 1—Air agitation installation.

Fig. 2—Baffle plate agitation.

especially if some of the soft metals are being cleaned, such as brass or copper. After cleaning, if the flow of the current is reversed for a few seconds, it has a tendency to remove tarnish from the metal. When cleaning flat surfaces of copper and brass, 3 or 4 seconds on direct current (using the work as the cathode) and 1 or 2 seconds on reverse current (using the work as the anode) is sufficient. When cleaning die cast metal the direct current (using the work as the cathode) only should be used. Usually 3 to 5 seconds in a mild cleaner is sufficient. If work has recesses which permit of accumulations of buffing compositions, it is good practice to remove these deposits by scrubbing before placing in the electric cleaner.

Electric cleaning tanks are entirely satisfactory where an absolutely clean surface is required, as for instance the preparation of a surface for an electro deposition of metal, but it is advisable, to insure best results, to use a soak cleaner first and then rinse off so that the electric cleaner is not mucked up with heavy grease and oil.

Different densities of alkali solutions govern the conductivity and, therefore, the amperes per sq.ft. of metal cannot be stated definitely. It ranges anywhere from 15-45 amperes per sq. ft. of metal; 6-12 volts are required. In figuring square feet of surface cleaned consider both sides of the metal. In selecting anode or cathode rods or hooks, consider their ability to carry the flow of amperes without resistance. The following table is for square soft copper rod (for round copper rods deduct 25%).

Size, In.	Ampere Capacity
1 x 1	750
1/2 x 1/2	188
3/4 x 3/4	47
5/8 x 5/8	12
3/4 x 3/4	1.6

Steel or iron should never be used for hooks to suspend work in a cleaning solution.

(4) *Steam and Alkali Spray*—Garages use a direct spray of steam and alkali solution for cleaning chassis and engines. This method may also be used for cleaning parts on locomotives. With this method a double-jet nozzle is used, one side connected to a high pressure steam hose and the other feeding by gravity from a tank of hot alkaline solution. The steam and solution are mixed in the nozzle and thrown with force on the metal, cleaning the spot very quickly. This method is also used quite extensively in stripping paint from automobile bodies.

There is now an alkaline vapor employed. A small boiler equipped with coils and heated by an automatic oil burner is used. A very weak alkaline solution is mixed cold in a separate tank and is pumped to the boiler and introduced at the top; passing down toward the oil burner, it is heated and broken up, and then passes out through a hose to the nozzle where it is applied to the work to be cleaned. Pressure may be adjusted and maintained up to 170 lb.

(5) *Metal Parts Washing Machines*—Metal parts washing machines offer a very practical method of applying an alkaline cleaning solution. Small work is placed in baskets or trays and large work is placed directly on the conveyors, which carry the work through the machine where the alkaline solution is pumped through sprays and either thrown with force over the metal or splashed in large quantities over it. The cleaning action is both mechanical and chemical, and may be increased or decreased by varying the strength of the solution.

If two washing machines are used, most of the oil and grease are removed in the first machine, thereby keeping the solution in the second machine free from refuse and in the best working condition. Besides having the second solution in the best working condition, the parts have been heated in the first machine, therefore, the final cleaning is more readily accomplished. In winter it is advisable to keep the work as warm as possible before cleaning, because large parts that are cold cool the cleaning solution, resulting in lost time.

Methods Employed with Metal Parts Washing Machines—The manufacturers of metal parts washing machines employ four different methods of application as follows:

- (1) The splash
- (2) The fixed spray
- (3) The revolving wash arm
- (4) The rotary drum.

(1) *The Splash*—In the splash method, a wheel similar to a side wheel on a steamboat is revolved on one or both sides of the conveyor. In this manner, large quantities of the cleaning solution are splashed with force over the work as it passes through the machine on the conveyor.

(2) *The Fixed Spray*—In the fixed spray, pipes provided with nozzles are placed above, below, and in certain machines on both sides of the conveyor. The cleaning solution is pumped through these nozzles, the jets striking directly on the work from every angle. The stationary location of the nozzles makes it possible to use a high jet pressure, which increases the mechanical cleaning action of the solution.

(3) *The Revolving Wash Arm*—In the revolving wash, a four spoked, slotted wash arm is used, through which the cleaning solution is pumped in large quantities onto the metal to be cleaned, as it passes through on the conveyor. On the end of each arm is an adjustable nozzle and this is set at an angle so that the force of the solution pumped through it makes the arm revolve. These arms are 16-30 in. long so that the work in passing through, goes through a solid wall of swirling solution, which hits it directly from every angle.

In both the spray and revolving types of machines, the tank is below or at the side of the conveyor and is heated by steam coils. The solution is used over and over. After the solution has passed over the work, strainer pans catch the heavy foreign matter which has been washed off and by a system of baffle plates in the tank, the solution is strained and filtered so that the solution pumped over the work is always clean.

(4) *The Rotary Drum*—With the rotary drum washing machine, the work is tumbled as it passes through a perforated drum. The work is moved forward by a helical screw as the drum slowly revolves. The washing solution is forced over the work from the inside of the drum through stationary sprays.

All these machines are thoroughly practical for cleaning before japanning and enameling, and before assembling or between machining operations or for removing quenching or tempering oils, but they are not practical as a cleaning method before electro deposition.

Pickling Iron and Steel Products

By C. H. McCollam* and D. L. Warrick†

General—Pickling is the term applied to the chemical removal of surface oxides from metal by immersion in an acid solution. Wide variations are possible in the strength, temperature, and type of the acid solutions used and the procedure depends upon the material to be pickled, the character of the scale involved and the surface desired after pickling. The following discussion will deal only with the pickling of ferrous metals.

Low carbon, hot rolled steel pickling is typical of the basic principle involved. In this case the surface oxide to be removed is mill scale formed at comparatively low temperatures during or after hot rolling. Removal of such scale is one of the simplest of the cleaning problems. The material is submerged in dilute sulphuric acid until free from scale, after which it is removed and rinsed. For purposes of economy and efficiency the acid concentration is held at approximately 10% and the temperature maintained between 150 and 190°F.

A container is required in which the acid and the material to be pickled can be held for a reasonable time at the desired temperature. To this basic piece of equipment has been added such operating conveniences as cranes, temperature control instruments, and mechanical agitators. The pickling tub or tank is subject to changes in construction which will be discussed further in another part of this article, as will pickling acids, inhibitors, foam producing agents, and rinses.

Pickling Procedures for Various Ferrous Metal Products—Although pickling appears to be a simple process, numerous refinements or modifications are necessary in many instances. Because of the broad influence of sometimes obscure variables in scale formation and because of the difference in processing practice and equipment encountered even in two plants making the same product, it is not practical to reduce pickling procedure to a standard formula. In certain instances, the problem has become so complicated that even the mechanism of scale removal by pickling has become a controversial subject. Therefore, the procedures described in the following paragraphs are merely the methods which have been found to be successful in plants producing the particular material under discussion rather than formulas which can be followed without modification.

Cleaning prior to pickling is often quite as important as the operation itself. The iron or steel is frequently covered with grease from previous fabricating processes which is not soluble in acid and renders pickling difficult. Hot alkali solutions are generally satisfactory for cleaning such material, but should always be followed by careful rinsing before the material passes on to the acid. Another cleaning method is to heat the metal to a moderately high temperature for a short time to remove the grease.

When low carbon steel is pickled for enameling, galvanizing, or tinning, special precautions are necessary to insure a surface which is chemically clean as well as free from scale. A slightly but definitely etched surface is often considered an advantage in such cases because it is believed to permit greater adherence of the coating to the metal. In this case inhibitors or foaming agents can be used in the bath only with careful selection and proper precaution, since some inhibitors leave a thin but very tightly adherent surface film which clings persistently to the metal even after careful rinsing.

The trend in recent years is toward lower pickling temperatures, around 150-160°F., resulting in economy in steam consumption and in better quality of the finished product. Where time and pickling capacity permit, an acid concentration of 5 or 6% is advisable. The usual practice, however, where comparatively low temperatures are used is to compensate for decreased thermal activity by raising the acid concentration to about 10 or 15%.

In the continuous production of sheet or strip steel, provision is usually made for continuous pickling so that fabrication can proceed without interruption. In this case, control of the rate of pickling is accomplished by varying the temperature

*Chief Chemist, and †Research Chemist, The Timken Steel & Tube Co., Canton, Ohio.

or the acid content of the bath, or both. Close supervision is necessary if efficiency and economy are to be realized, since the acid content of the bath is constantly changing. Acid concentration and temperature are frequently kept too high for best results in economy or quality in order that the operation may be completed in the time allowed.

In pickling for galvanizing or tinning many plants use two pickling baths: First a 5-10% solution of sulphuric acid in water at 150-190°F., and second, a short time dip in cold concentrated muriatic acid (18-20° Baumé) or in a moderately strong solution of muriatic acid at a somewhat elevated temperature. The use of high temperatures with muriatic acid is wasteful since this acid has a strong tendency to evaporate, filling the atmosphere with noxious fumes.

Vigorous mechanical agitation of the bath is always advisable. When it is allowed to remain stagnant, gas pockets tend to form which keep the acid out of contact with the metal and arrest the pickling action on these localized areas. When the steel is galvanized, these scale-retaining areas remain uncoated. Agitation offers the further advantage of securing uniform acid concentration throughout the bath, assuring a more nearly uniform rate of pickling.

When pickling sheets for galvanizing or tinning, as short a time as possible should elapse between pickling, rinsing, and coating operations. Should a delay occur between rinsing and coating the material should be stored under water and never allowed to dry. Contact of the moist iron with air will produce rusting. Furthermore, any ferrous salts from the pickling bath which dry on the work become oxidized and difficult to remove.

When pipe or seamless tubes are to be pickled, particularly those of small inside diameter, high acid concentration is advisable, since the acid solution which first enters the tube must often be relied upon to complete the pickling of the inside surface. Occasional lifting of the bundle above the bath to drain the spent acid out of the tubes helps to overcome this difficulty. Jets of air or steam directing a current of pickling solution through the tubes are sometimes a valuable aid. Mechanical rockers may also be used to advantage in the removal of thick or tight scale.

Heat treated material introduces many special pickling problems. It has been demonstrated that when alloy steels are heated above a certain critical temperature which varies with the type of steel, an electrolytic action is set up between the scale and steel during pickling. This action proceeds at the expense of the clean metal and results in serious pitting of the surface. Inhibitors have been found to be of little value in preventing such pitting. Normalizing scale represents the worst condition as far as pickling time and pickle pitting are concerned, while temper scales are the easiest to handle. Best results will usually be secured by using a fresh bath of 8-10% sulphuric acid (inhibited) with a temperature of between 145°F. and 155°F., and providing mechanical agitation.

Forging scale, like heat treat scale, is hard to remove. The scale formed at elevated temperatures is likely to be thick, glassy and extremely adherent. Scale is likely to be knocked off while handling, leaving small exposed areas of metal. At such places deep pickle pitting is likely to occur. However, when the scale is removed from large areas of metal prior to pickling the pitting is much less severe. The mechanical removal of as much of the scale as possible either before or during pickling decreases pitting. Pickling in 8-15% sulphuric acid at 150-160°F. has been found to give good results.

Pickling Stainless Steels—Stainless steels present a special pickling problem because scale containing high percentages of chromium oxides is not readily attacked by sulphuric acid alone. A common practice for stainless steels is to employ a mixture of about 10% sulphuric acid with 2-10% muriatic acid or a mixture of 10% sulphuric acid with about 10% of common salt. In the latter case, muriatic acid is generated by reaction between the sulphuric acid and the salt. Muriatic acid alone is sometimes used. In either case the pickling is followed by a bright dip in 5-50% nitric acid by volume. The more dilute solutions of this acid are generally used warm while the higher acid concentrations should be used cold because high concentrations of nitric acid are detrimental to many materials used in constructing pickle tubs. Thorough rinsing in hot water, sometimes augmented by scrubbing, is essential for best results.

Equipment—The pickling tank may be constructed of wood, steel, brick, concrete, lead, Monel metal, or stainless steel. Steel and concrete tanks are generally lined with some acid resisting material, while wood, brick, or alloy metal tanks are either lined or unlined, depending upon the service for which they are intended and the cost factor.

Wooden tanks are the cheapest to construct. They are generally made from cypress or long-leaved yellow pine. A bitumastic or similar lining of asphalt material is often used between the walls. Brick tubs, may be of common or acid proof brick, with or without mastic lining material between courses. Rubber linings may be used on wood or steel tanks. Monel metal and stainless steel offer many advantages but the cost is generally prohibitive. Steel tanks, brick sheathed and rubber lined, are satisfactory for most uses.

Acid Storage Tanks—For the storage of sulphuric acid down to 58° Baumé mild steel tanks can be used. Muriatic and hydrofluoric acid are generally stored in lead lined tanks.

Acid lines carrying concentrated sulphuric acid of 58° Baumé or higher from the storage tank to the pickle tub may be of iron pipe with iron fittings. Care should be taken to calk all the joints with a good acid resisting material. Sections of pipe which are immersed in the pickling bath should be made of lead, copper, or bronze. Heavy rubber hose is sometimes employed. Stainless steel lines are satisfactory for strong nitric acid.

When copper or bronze is used in connection with pickling equipment, there is always the possibility of electrolytic deposition of copper on the pickled surface. Ordinarily this is of no consequence, but if the stock is to be carburized without machining after pickling, the copper film will prevent carburization. Copper stains on full finished sheets are also objectionable. The use of copper or bronze in the pickling tub would be objectionable in such cases.

Drainage lines should be of vitrified tile carefully calked with an acid proof cement to avoid leakage, and should be large enough to provide adequate drainage at all times. Floors surrounding the pickle tubs should be covered with a wooden lattice, preferably of cypress.

Agitation saves time, metal, and acid. Air, steam, or mechanical movement of the tub or charge may be used, each having certain advantages. Some plants mount the tub on rockers, others support the charge on chains or saddles of acid resistant metal which impart a continuous or intermittent motion to the work. Another system involves the use of a large plunger which alternately raises and lowers the liquid level in the tub. Small articles may be pickled in a tumbling barrel. No definite recommendation can be given, for the means of securing agitation in the pickling tub will depend upon the size and kind of material being treated, the equipment available, and the character of result to be secured, thus making each installation an individual problem.

Adequate Ventilation should be provided when the pickling room is designed and should be maintained at all times. Ventilating equipment should be of acid proof material.

Pickling Solutions—Acids and acid mixtures generally used are sulphuric, muriatic, nitric, and hydrofluoric, or mixtures thereof. Sulphuric acid is the cheapest and most commonly used pickling acid. Muriatic acid is used for special purposes such as etching prior to galvanizing or tinning and sometimes for stainless steel. Nitric acid is used in the pickling of stainless steels and it is occasionally employed to oxidize scaled surfaces to facilitate pickling. Hydrofluoric acid is sometimes added to the bath to accelerate pickling, and is used occasionally in pickling castings to remove sand.

Acid Concentration—The action of the pickling solution on the metal is in approximately direct proportion to the acid concentration up to about 25% acid by weight. The concentration used depends upon the kind and temperature of acid, the type of material being pickled and surface desired. Thus when sulphuric acid is used on mild or pearlitic alloy steels the maximum concentration is 20-25% and the optimum is 8-10%. For pickling tubes and pipe a high acid content should be maintained because the solution on the inside of the tube does not circulate and consequently becomes depleted before the scale is removed if weak acid is used. Muriatic acid solution is held from 5-50% by volume. The higher concentrations of this acid cause definite etching of the surface. Nitric acid is used in amounts

of from 5-50% by volume. Concentrated solutions of nitric acid have a passivating effect on steel surfaces. The fumes from nitric acid are dangerous and adequate ventilation should be provided.

Testing of pickling solutions is an important part of pickling supervision and one that is frequently overlooked. Pickle tanks should be sampled regularly. It is a good plan to take a sample from each acid tank early in every turn. In the pickling of sheets the acid strength should be determined after each lift in batch pickling, and every 30 min. in continuous pickling. For testing the acid and iron contents a sample can be titrated with standard solutions. The use of a hydrometer for checking pickling solutions is not recommended, due to variations in gravity introduced by the ferrous sulphate content. The following procedures can be used for titrating pickle solutions.

Determination of sulphuric acid content. Measure out 5.0 ml. of pickle solution into a 200 ml. flask. Add 25 ml. of water and 2 drops of methyl orange solution. Add standard sodium carbonate solution until the last drop causes the color of the pickle solution to change from red to yellow. Each 5 ml. of the sodium carbonate solution equals 1% of sulphuric acid in the pickling tank. (This simple rule, which is sufficiently accurate for commercial purposes, is based on the specific gravity of 10% sulphuric acid.)

To make up the standard sodium carbonate solution, dissolve 11.52 g. of dried c.p. sodium carbonate in 1000 ml. of distilled water. (This standard solution is slightly stronger than N/5 sodium carbonate solution, which may be substituted without appreciable error in commercial practice.)

Methyl orange solution may be made up by adding 1 g. of methyl orange powder to 1000 ml. of distilled water. This solution should be kept in a dropping bottle.

When the pickling solution is muriatic acid the determination may be carried out in exactly the same manner as outlined above for sulphuric acid except for the final calculation. In this case each 5 ml. of the standard sodium carbonate solution equals 2.07% by volume of 20° Baumé muriatic acid or 2.36% by volume of 18° Baumé acid, each of these values being equivalent to 0.755% by weight of hydrogen chloride. (Based on the specific gravity of 10% hydrochloric acid solution.)

Determination of Iron Content—Five ml. of pickle solution is placed in a 200 ml. flask and diluted with 5 ml. of water. Standard potassium permanganate is added from a burette until the last drop turns the pickle solution to pink. Each 5 ml. of standard permanganate solution equals 1% of iron or 5% of ferrous sulphate. The pink endpoint fades quickly when organic inhibitors are present, therefore, the titration should be carried to completion as rapidly as possible.

The standard potassium permanganate solution can be made by dissolving 6.01 g. of c.p. potassium permanganate in 1000 ml. of distilled water. (This standard solution is slightly weaker than N/5 potassium permanganate, which may be substituted without appreciable error in commercial practice.)

Acid Addition—The acid content should be maintained at all times above the minimum found to be practical for the material being pickled. For mild carbon steel and most alloy steels requiring a sulphuric acid solution this would be about 5% of acid. Acid additions should be made frequently and in small amounts to hold the bath uniform. The bath should always be agitated when acid additions are made to assure thorough mixing.

If acid consumption is to be accurately established many factors must be considered. The acid addition must be carefully measured, either by metering or by means of a measuring tank. When additions are recorded as being so many "minutes of acid" through a pipe, there are generally variations due to the amount of acid in the tank, the air pressure on the acid line and other factors. Variation in the size and shape of material being pickled has considerable influence on acid consumption.

Changing of Pickle Solutions—The damping effect of ferrous sulphate on pickling bath efficiency is well known. The ferrous sulphate content of a bath is five times the iron content; and it has been demonstrated that with 40% ferrous sulphate (8% iron) the rate of attack of sulphuric acid on steel is reduced 50%. It is common practice to run the ferrous sulphate content up to 25% (5% iron), then use the solution until the acid content is reduced to less than 5% and dump the tub.

Disposal of Waste Liquor—The practice of dumping waste pickle solutions into sewers and streams has resulted in stream pollution. Legislation has been introduced in many states requiring the neutralization of pickling acid before disposal.

Recovery plants may be installed in connection with large pickling installations for recovery of acid and salvage of iron compounds. Such plants are expensive to build and maintain and consequently their application is limited. Smaller pickling plants find it more economical to kill the spent acid with lime in settling basins.

Pickling Temperatures—The heating of pickling tanks is generally accomplished by introducing live steam through an open or perforated lead pipe. Temperatures can be taken at intervals by an ordinary thermometer or indicating or recording instruments can be installed for this purpose. Temperature controls are available for installations where temperature variation must be held to a minimum.

The effect of temperature on the activity of the pickling bath is generally recognized. Sulphuric acid at 190°F. has over 100 times the solution rate of the same acid at room temperature. Overpickling is likely to occur at high temperatures. The use of an inhibitor is an important factor in establishing the limiting temperature since some inhibitors fail rapidly at high pickling temperatures.

While a temperature of 170-190°F. is sometimes satisfactory when the time cycle is short, pitting may result if the pickling period is prolonged. With many high carbon and alloy steels a pickling temperature of 140-150°F. has been found to be satisfactory for efficiency, surface quality, and inhibitor life.

Pickling Inhibitors—Definition—Pickling inhibitors are agents which may be added to an acid pickling bath to diminish the attack of the acid on the metal areas from which the scale has been removed, without appreciably retarding the rate of scale or rust removal by the acid, and to diminish the severity of hydrogen embrittlement.

Theory and Mechanism of Inhibitors—The actual mechanism of inhibitor action is not well understood. Some investigators believe that inhibitors are negative catalysts that are selective in action, retarding the reaction of acid on metal but not on scale. In practice no inhibitor continues its original effectiveness unabated throughout the entire pickling cycle. However, they lose efficiency so slowly that the loss could hardly be attributed to reactions in which the inhibitor plays a major part as reagent. The effect seems analogous to the familiar poisoning of a catalyst.

Various observers have stated that inhibitor action seems to be associated with an increase in the hydrogen overvoltage at the metal (cathode) surface. A protective coating of hydrogen is thereby maintained on the metal surface which helps to protect the metal from direct contact with the acid, thus diminishing the attack.

Another theory is that a thin layer of inhibitor material is adsorbed or plated out on the surface of the metal. Many of the known organic inhibitor solutions are colloidal in nature, which lends support to the possibility of either adsorption or cataphoretic migration of inhibitor particles. On the other hand, such a layer, if existent, is so extremely thin as to escape detection in many instances.

Nature and Composition of Inhibitors—A wide variety of materials have been advocated and used as inhibitors, from cabbage leaves or wheat bran to complex synthetic organic chemicals. In numerous instances raw materials and by-products have been found to be useful as inhibitors, and many are still being used without the separation or identification of the active ingredient. A comprehensive list of such materials would be difficult to prepare, but would include the following: Sludge acid from oil refineries, waste animal materials, waste sulphite cellulose liquor, wheat bran or off-grade flour, sulphonation products of such materials as wood tar, coal tar, and asphaltum. These materials vary widely in their effectiveness and uniformity. They have an economic advantage and are not necessarily inferior to synthetic inhibitors.

A wide range of synthetic chemicals have been reported as showing inhibitive properties. Many of these are extremely complex in structure and high in molecular weight. Aldehydes, thioaldehydes, mercaptans and other sulphur-containing organic compounds, organic nitrogen bases and their derivatives, particularly those in which the nitrogen is linked within a heterocyclic ring, such as pyridine and quinoline, seem to be favorites. Their cost often precludes their use for production

work. Some of these compounds are so efficient, however, that extremely small amounts are required.

Foaming Agents—The function of foaming agents is to blanket the surface of the pickling solution with a suds which traps and holds any fine spray of acid that would otherwise be carried into the atmosphere with the hydrogen gas evolved. Their chief advantage lies in their ability to prevent the pollution of the atmosphere with acid fumes.

Confusion still exists in the minds of many concerning the relation between inhibitors and foaming agents. Actually they represent independent phenomena, although in many preparations they are co-existent. When sufficient quantity of a good inhibitor is used the evolution of hydrogen gas is so small that the use of a foaming agent becomes practically unnecessary.

Methods of Testing Inhibitors—Because of the wide variety of inhibitors and their diversity of behavior, it is important to have some method of testing their efficiency. While the ultimate test is their behavior in the pickling bath, laboratory tests offer a convenient means of comparing the value of inhibitors under carefully controlled conditions.

Laboratory tests for inhibitors are of two general types: (1) Those which measure the loss in weight of metal in inhibited acid, and (2) those which measure the amount of hydrogen evolved. The latter test depends on the fact that when metal reacts with a nonoxidizing acid hydrogen is evolved, but when the acid reacts with metallic oxide, water is formed with no gas evolution. Hence a theoretically perfect inhibitor should allow removal of the scale with no evolution of hydrogen.

Inhibitors frequently fail in service due to localized overheating. This occurs at the point where steam is introduced into the bath. Laboratory tests should take this fact into consideration. A satisfactory check may be secured by refluxing a sample of the inhibited pickle solution for not less than 1 hr. Because of the wide difference in the acid solubilities of high and low carbon steels, inhibitor efficiency tests should be made on the same grade of steel as will be treated in the pickle tub.

Advantages and Disadvantages of Acid Inhibition:

Advantages:

1. Reduces metal loss.
2. Saves pickling acid.
3. Prevents or minimizes scrap losses resulting from overpickling.
4. Decreases blistering and hydrogen embrittlement.

Disadvantages:

1. Increased pickling time.
2. Possibility of residual surface film which may interfere with subsequent operations.
3. Added cost of inhibitor.

Washing and Liming After Pickling—The importance of a clean rinse tub is not always appreciated. Ferrous sulphate gradually accumulates in the rinse water. Traces of ferrous sulphate which remain on the steel after rinsing will oxidize upon drying, leaving a film of rust on the surface. Acid also tends to accumulate in the rinse tub and promotes rusting of the steel on exposure to the air.

Complete removal of the last traces of acid with water alone is difficult even with thorough rinsing in clean tubs. When pickled steel must be protected from rust, an alkaline rinse to remove the last traces of acid is advisable. A solution of $\frac{1}{2}\%$ of caustic soda and $\frac{1}{4}\%$ of trisodium phosphate ($\text{Na}_3\text{PO}_4 \cdot 12\text{H}_2\text{O}$) in hot water is effective. The alkalinity of the bath should be checked frequently and maintained by the addition of caustic soda. Acid titration (methyl orange indicator) is the best means of determining the alkalinity. Five ml. of the above alkaline solution should require 5-10 ml. of N/10 sulphuric (or hydrochloric) acid for neutralization.

A cold dip in milk of lime is also effective for neutralizing traces of acid. This method leaves a coating of lime on the surface which is not easily removed. In pickling prior to cold drawing operations this is an advantage because the lime acts as a lubricating agent.

The presence of a white suspension of solid material is not proof that sufficient lime remains in the solution. Calcium sulphate, formed when lime reacts with sulphuric acid, is a white powder which is only slightly soluble in water, and may easily be confused with lime. Titration of the available alkali with a mineral acid gives a positive index of the lime content of the solution.

Pickling Defects—Pickling is frequently blamed for certain defects which appear during the pickling operation but which have their inception elsewhere. The tendency is to blame all failures on overpickling or to condemn the steel as being defective. Certain defects, however, are due to neither of these causes, but are the result of earlier operations such as rolling, heat treating, or forging.

Overpickling is characterized by porosity of the transverse surfaces and a roughening of the whole surface, with discoloration and decrease in size and weight. This can be avoided by removing the material from the bath promptly when pickling is complete. Inhibitors aid in preventing overpickling, but are not a complete guarantee that it will not occur.

Pickle pitting may be classified into several different types according to cause. Three of these are sufficiently common to justify special consideration.

By far the most prevalent and troublesome type of pitting, particularly on heat treated alloy steels and forgings, is electrolytic. This is characterized by a patchwork of pitted areas of irregular shapes, the depth being indirectly proportional to the area. Such pitting is due to an electrical potential between the scaled areas and clean steel, the pitting occurring only where the scale is removed from small areas prior to pickling or at an early stage in the process. It should be noted that the pitted areas frequently are longitudinally aligned. The boundaries of such pitted areas are usually rather sharply defined or channeled, probably due to maximum potential existing at such locations. However, when inhibited acid is used the pitted area is generally uniform in depth, with a channeled boundary, while in uninhibited acid the pitted area is irregular in depth.

Although it seldom occurs, severe pitting may be caused by overpickling, particularly in inhibited acid. This is indicative of carelessness on the part of the pickler because it appears only when material is allowed to remain in the bath far beyond the time necessary for complete removal of scale.

Pits which have their origin in the rolling process, due either to rolled-in scale or refractories are intensified during pickling.

Nonmetallic inclusions, segregated carbides, or surface strains are frequently held responsible for pickle pitting. While these factors may have some influence, their importance has been overstressed and it is always advisable to first investigate the causes discussed in the preceding paragraphs.

Blistering is a troublesome defect on sheet and strip steel. Of the several theories advanced concerning the origin of blisters the most reasonable seems to be that they are due to gaseous inclusions in the steel, forming gas pockets just beneath the surface upon rolling. Hydrogen generated in the pickling operation penetrates these pockets and lifts the surface, causing a blister.

Properly selected inhibitors may minimize blistering but it is doubtful that they will entirely prevent it.

Hydrogen embrittlement is a phenomenon that gives some trouble when cold working operations follow too soon after pickling. It seems to be due to the intermolecular penetration of the steel by nascent hydrogen. This type of embrittlement is not permanent and may be eliminated by aging or more rapidly by soaking the steel in boiling water. Inhibitors are valuable in minimizing this effect.

Safety—Strong acids and alkalis cause severe burns if not counteracted promptly, and are destructive to clothing. A supply of cold running water should be available at all times for washing. It is important that large amounts of water be used, for when small amounts of water are added to concentrated sulphuric acid much heat is generated which may add to the severity of the burn. Safety showers with a platform release are recommended in this connection as providing the necessary volume of water in an emergency.

To remove the last traces of acid from the skin after thorough rinsing with cold water use sodium bicarbonate or baking soda, either dry or mixed with water. In case of severe injury consult the medical department for further treatment. Ammonia may be used on clothing, but should not be used on the skin.

To remove traces of alkali left after washing with cold water use powdered boric acid or a saturated solution of boric acid in water. Consult a physician for further treatment.

Hydrofluoric acid burns are exceedingly severe and painful, hence the utmost care should be used in handling this acid to prevent any contact whatsoever with the skin. Material being pickled in this acid should never be handled without rubber gloves.

Electrolytic Pickling of Iron and Steel

By Walter R. Meyer*

Electrolytic pickling of iron and steel has been employed for a number of years to escape some of the difficulties attendant with still pickling. The removal of rust as Fe_2O_3 is comparatively easy with still pickling methods, but the removal of the black magnetic oxide of iron, namely, Fe_3O_4 , which is slowly soluble in sulphuric acid, is a difficult problem without the use of electrolytic methods. Before discussing specific electropickling processes, some general problems such as the nature of scale and its removal, and hydrogen embrittlement will be considered.

The Nature of Fire Scale and Its Removal—The black oxidation product of iron which results after the heat treatment of iron or steel and commonly called "fire scale" or "hammer scale" is composed, according to Winterbottom and Reed,¹ of 80% FeO , 18% Fe_3O_4 , and a top layer of Fe_2O_3 . The composition of fire scale on hot rolled stock and heat treated parts may vary considerably from this analysis, but the important point to consider is that the composition of the scale varies from ferrous oxide at the metal interface to magnetic oxide with a thin layer of ferric oxide. Hering² has found that the magnetic oxide is hardly attacked by sulphuric acid, but that hydrogen either formed electrolytically or by the attack of the basis iron by the acid leads to rapid dissolution of the scale. The probable mechanism of fire scale removal is an acid attack on the ferrous and ferric oxides, partial reduction of the magnetic oxide and the dissolution of the reduction products, the reduction resulting from the electrolytically formed hydrogen or in the case of still pickling by the action of the acid on the iron, and lastly a resultant undermining of the residual scale with some mechanical lifting action provided by the discharged hydrogen.

Advantages of Electrolytic Pickling Over Still Pickling—The electrolytic pickling processes are far more rapid than still pickling, requiring in most cases from 1-3 min. for completion, whereas still pickling may require from 10-15 min. for the same type of scale. Much less acid is consumed in electropickling than still pickling the consumption being according to Thompson and Mahlman³ about 50% less for electrolytic than still pickling. The savings in iron and acid usually outweigh the added cost of power for electrolytic pickling. The scale reduction efficiency of the electrolytically formed hydrogen varies from 10-50%, being most efficient at 50°C. and at a current density of 50 amperes per sq.ft.

The attack on the base metal and in some processes the hydrogen embrittlement is much less for electrolytic pickling than with still pickling. These features are important where size tolerance must be maintained and where the ductility must not be greatly impaired. Other specific advantages will be considered with the discussion of the various processes.

Some disadvantages of electropickling are the cost of equipment for the generation of the electric current, necessity of maintaining good electrical contacts, and the need in some cases of controlled temperature and concentration of acid to a greater degree than is required with still pickling. In some cases, the acid dragout losses are much higher for electrolytic pickling as the concentration may have to be maintained above 85%, whereas still pickling is done with much more dilute acid concentrations.

Hydrogen Embrittlement—Simple cathodic pickling may result in hydrogen embrittlement either equal to or greater than that which results with still pickling, but some of the special electrolytic processes, however, may result in little embrittlement. In general, hydrogen embrittlement is greater with increasing carbon content of the steel, higher temperature of the pickling bath, higher hydrogen over voltages, and may be accelerated by traces of impurities as arsenic, mercury, or sulphur compounds. With the same amount of discharged hydrogen the strength of acid used has little effect on the embrittlement.

The original ductility of the steel may be almost completely restored by heating for 2 hr. at 100°C., 10 min. at 150°C., or by immersing in boiling water from 2-5 min. Gradual recovery may occur on standing for several days at room temperature, but in all cases of treatment the original ductility is never completely restored.

*Managing Editor, Metal Industry, New York.

The Madsenell Process—The Madsenell Process⁴ employs anodic electropickling to remove absorbed gases and carbon smut to secure an excellent surface for adhesion of electrodeposits or hot dipped coatings. The work is first cleaned and pickled either with the conventional still methods or electrolytically and then transferred to the Madsenell "degassing" bath. The electrolyte is sulphuric acid of concentration greater than 85% maintained from room temperature to 100°F. The work is made the anode with the current on when immersed. A 12 volt line is usually employed which provides a current density of 50 amperes per sq.ft. initially, but which drops within from 30 sec. to 10 min. to almost zero current with resultant cessation of the gas evolution.

The work has then been effectively cleaned of surface smut and has been degassed to a large measure of hydrogen which may cause embrittlement. The merit of the Madsenell Process lies in its ability to remove some of the effects of the pickling of the fire scale rather than being a method designed for the scale removal itself. Some possible disadvantages may be the necessity of maintaining a high acid concentration in the bath, the need of direct current generators or rectifiers, and the maintenance of good electrical contact.

The Hanson-Van Winkle-Munning Electrolytic Bright Dip—This process⁵ is carried out in two steps. The work is first made the cathode in a warm dilute sulphuric acid bath of from 10-20% acid at a current density from 10-150 amperes per sq. ft. for several minutes. The scale is effectively removed but the work may be coated with an "acid black". To remove this smut the work is rinsed and transferred to a stronger acid bath (40-50%) where it is made the anode for a short time employing a current density from 100-150 amperes per sq.ft. The total time required may vary from 2-5 min.

High current densities and low temperatures (50-90°F.) are favorable to the production of a good bright surface. With too low a current density or too high a temperature, the surface will be clean but not bright although higher temperatures can be offset to some extent by using higher current densities. The production of the bright surface may be due to the formation of persulphuric acid which is favored by low temperatures and high current densities. The current density referred to is the initial value as polarization sets in rapidly and the current density drops quickly with a cleaning and then a brightening of the work.

The process imparts a silvery surface free from smut and scale with only a small degree of etching and a considerable reduction in embrittlement due to the anodic treatment. The need of good electrical contacts for maintenance of high current density and the necessity for cooling the acid for the anodic treatment must be considered.

The Bullard-Dunn Descaling Process—The Bullard-Dunn Descaling Process⁶ has found extensive use in removing scale from heat treated parts without attacking the base metal. After removal of oil, the article to be descaled is made the cathode in a 10% sulphuric acid bath heated to 140-150°F. and electrolyzed at a current density of from 60-75 amperes per sq.ft. A small quantity of tin or lead is maintained in the bath which results in a deposition of a thin film of either metal as soon as a bare section of iron is exposed. The deposition of tin protects the steel from acid attack and adds "throwing power" to the cleaning process because of the high hydrogen over-voltage of tin. The current discharge is consequently directed to the section covered with scale where the hydrogen exerts both a reducing effect and a mechanical action to lift off the scale. Deep recesses, threaded parts, and irregularly shaped objects are readily descaled and coated with a thin layer of tin or lead which helps to protect the metal from subsequent corrosion and does not interfere with machining or in the case of tin, with hot galvanizing or hot tinning. For electroplating or other cases where the tin or lead must be removed, the work is made the anode in a hot solution of caustic soda and trisodium phosphate where the protective film removal is accomplished in a short time.

The use of ferrosilicon anodes such as Duriron⁷ in the descaling bath lengthens its life considerably because of their ability to prevent the formation of ferric iron, the presence of which rapidly decreases the efficiency of the bath. Iron concentrations as high as 10 oz. per gal. will not destroy the effectiveness of the bath as long as they are in the ferrous condition. A large portion of the ferrous sulphate may be removed by chilling the solution. From 1-2% of the total anode surface is block

tin to allow a constant feeding of tin to the bath to compensate for that which is plated out in the descaling process.

The operation of this process is not particularly critical as to current density or composition of solutions, scale removal is rapid, the attack on the base metal is almost negligible, and its ability to remove scale from recesses is excellent.

Pickling of High Speed Steel—High speed steels containing tungsten, chromium, and vanadium are pickled with difficulty in nonelectrolytic pickles. R. R. Rogers¹ has reported a process which involves anodic pickling at 25 amperes per sq.ft. in a bath at room temperature containing 15-16 oz. per gal. of caustic soda and 2 oz. per gal. of citric acid. The electrolysis is continued for a few minutes until a uniform evolution of gas sets in which denotes the end of the pickling process. The work is removed, rinsed, and then dipped into strong hydrochloric acid (6-12N) to remove a smut which formed in the anodic pickling.

Some high speed steels may require a preliminary anodic treatment at 60 amperes per sq.ft. in 6 N hydrochloric or sulphuric acid before subjecting them to the alkaline anodic treatment. For both high speed steels and carbon steels, anodic pickling in hydrochloric acid results in an attack upon the metal itself whereas in sulphuric acid the attack is largely upon the scale.

The Ferrolite Pickling System—The Ferrolite pickling process² utilizes alternating current for pickling in a sulphuric acid solution varying in acidity from 5-10%. Ten per cent by volume of the total acidity of the bath is made up of gluconic acid or a mixture of organic sugar acids. Graphite electrodes are used and the work is dumped in acid resisting baskets and lowered between the 2 electrodes without making actual contact with either electrode. Sixty cycle alternating current is passed through the solution and the work is completely pickled in a short time. Deeply recessed articles are readily freed of scale.

The gluconic acid serves as an agent for the solution of ferrous oxide and as a regenerative catalyst for the regeneration of the inorganic acid ions, in this case the sulphate ion. The sulphuric acid serves as a carrier of the current and to attack the oxides of iron.

Choice of Method for Pickling—No attempt has been made to select or favor any one method of pickling as it is the purpose of the Handbook to give sufficient information to allow the user to judge for himself the relative merits of each process for his own particular problem. More detailed information can be obtained from the patent owners of the processes cited below and the original literature.

Cleaning Metals by Blast Cleaning Process

(Also Known as Sand Blasting, Grit, and Shot Blasting)

By Victor F. Stine*

Introduction—The process of blast cleaning metals is one whereby sand or metal abrasives (grit or shot) propelled by air or other means is directed at the surface to be cleaned. The method of application varies with the individual requirement. The centrifugal method has recently come into use. In this process, metal abrasive is thrown on the surface to be blast cleaned by means of a centrifugal force whereby the abrasive is thrown by a wheel at a high speed. This process is limited to metal abrasive because the sp.gr. of sand is too low for the centrifugal force to do as efficient cleaning as is possible with the much heavier metal abrasives.

Types of Air Pressure Blasts—There are two major types or principles used in air pressure blasting:

1. Direct Pressure type.
2. Induction type.
 - (a) Gravity principle.
 - (b) Suction principle.

Direct Pressure Type—In applying the direct pressure principle, the full pressure of compressed air is carried all the way to the tip of the nozzle. In order to introduce the abrasive into this high pressure line, it is necessary to provide a pressure storage tank in which a certain amount of abrasive is also under pressure. Through an orifice in the bottom of the tank, the abrasive is permitted to flow by gravity into the high pressure abrasive line (the pressure in the tank and line being equal). In actual practice, the apparatus often is more complicated by the introduction of adjustable orifices, shut-off means for the abrasive and air, and double chamber arrangement for obtaining continuous operation.

Gravity Type—The gravity method provides an overhead abrasive storage or other means of supplying abrasive by gravity to an induction type of gun, in which air is introduced through a jet which is in definite spaced relationship to a nozzle. The air rushing from the jet into the nozzle creates a partial vacuum in the space surrounding the gap between jet and nozzle. The abrasive introduced into this gap is sucked into the nozzle and there mixed with the compressed air, which accelerates the movement of each grain. At the nozzle tip, the air suddenly expands, pressure is transformed into velocity and the grains receive a last and quite effective "shove," so to speak. This principle, while not as effective as the direct pressure blast, is nevertheless frequently used owing mainly to its lower initial and maintenance costs.

Suction Type—The use of suction is similar to the use of the gravity type, and while somewhat less effective than the latter, finds even more application particularly in the design of automatic equipment for treating materials easily cleaned. An air jet and a nozzle are again in definitely spaced relationship, but contrary to the open hopper or funnel type of mixing chamber used in the gravity type outfit. These parts are enclosed in a body generally called "gun." An outlet is provided at some point with provision for attaching an abrasive hose or pipe line which leads to an abrasive feeding device, often many feet away. The partial vacuum inside the gun creates a strong suction in the abrasive line, which is sufficient to lift the abrasive entering the end of the hose or line for considerable distances. However, to lift this abrasive, energy is required which is lost for useful work. This accounts for the fact that this principle is the least effective of the three.

Blast from Blower—The medium of force in another method of blast cleaning is generated by a specially designed blower, which blows air at approximately 30,000 f.p.m. through a nozzle, into which approximately 10 times as much abrasive is fed as when using compressed air through a standard $\frac{3}{8}$ in. nozzle. Surfaces are cleaned by a scouring action. It is claimed that the power and maintenance costs are very low. The cleaning efficiency may not be so great as that of high pressure air blasting or centrifugal blasting.

Nozzles—A small, but important part of all blast cleaning equipment, is the nozzle. Nozzles are subject to wear, both at the inlet as well as at the outlet. The

*Second Vice-Pres., Pangborn Corp., Hagerstown, Md.
This article not revised for this edition.

wear at the inlet is of concern because the size of the inlet controls the air and power consumption.

A new $\frac{3}{8}$ in. nozzle, for instance, permits the flow at 90 lb. pressure of about 211 cu.ft. of free air, requiring 40.5 hp. for its production. If permitted to wear at the inlet to $\frac{1}{4}$ in., the air flow increases to 288 cu.ft. or 35½%, and the power to 54.9 (also 35½%). It is, therefore, readily seen that it may prove to be bad economy to use a nozzle too long, particularly in equipment using multiple nozzles. The wear at the nozzle tip is much more rapid than at the inlet. It is caused by the expansion of the air, which carries a certain amount of abrasive with it, tending to force it against the nozzle walls. This also explains why abrasives of lighter sp.gr. will wear a nozzle faster than the heavier abrasives. Each moving abrasive particle has a certain kinetic energy, which is directly proportional to its weight or mass. If it were possible to fire from a double barrel gun during a windstorm a cork ball and a lead ball simultaneously, the cork ball would be deflected from its course much more rapidly than the lead ball. Similarly, the side thrust exerted by the expanding air acts quicker upon the lighter grains than upon the heavier ones.

Another cause for the rapid wear upon nozzles caused by the lighter abrasives such as sand or artificial abrasives, is the fact that they travel through the nozzle faster than the heavier steel abrasives, because it is easier for the compressed air to accelerate a lighter particle than a heavier one. This higher velocity causes a larger volume of abrasive to flow in a given time, resulting in more frictional wear.

It goes without saying that granular abrasives (meaning abrasive grains which have sharp corners) cause more nozzle wear than globular grains, for example, grains of essentially spherical shape, such as metal shot. What was said about nozzle wear is also applicable to the wear of all other parts through which abrasive flows, the least wear being encountered when metal shot or grit is used. The length of the nozzle will give a more concentrated stream, whereas a short nozzle covers a larger area but shows a slightly higher abrasive velocity.

A successful attempt to reduce nozzle wear has been made with the introduction of so-called "long wear nozzles," with a tungsten carbide liner. These nozzles last about 300 hr.

There has recently been put on the market a nozzle with a liner known as boron carbide. This is said to be the hardest material made, only surpassed in hardness by the diamond.

Finishes—Almost any desired finish can be had by using the proper abrasive or mixture of abrasives. The illustrations show material cleaned with the three abrasives referred to: Metal shot, metal grit, and sand.

Shot

Grit

Sand

Surfaces cleaned with three types of abrasives.

Type and Sizes of Blast Cleaning Equipment—There are various types and sizes of blast cleaning equipment, the proper selection of which depends on the work to be cleaned and the production desired.

Air Pressure—For ferrous metals the pressure used ranges from 60 up to 100 lb., depending on the degree of cleaning required and the condition of the work. For nonferrous metals the pressure is from 10-60 lb., also depending on the nature of the work and degree of cleaning. On blast work for design or frosting effect, the air pressure is usually from 3-15 lb.

Tumbling, Rolling, and Barrel Burnishing

By Dr. R. W. Mitchell*

Introduction—Metal parts, after fabrication, often are cleaned, rinsed, rolled, and ball burnished and dried all in one sequence of operations. The words "tumbling" and "rolling" are often used synonymously. There is, however, some distinction between the two processes and the words may be used to differentiate between two operations, similar in general but differing in detail.

Tumbling, or rumbung, is an operation in which the work (usually castings or forgings) is rotated in a barrel, drum, or chest, together with stars, jacks, slugs, metal punchings, or some abrasive such as sandstone or granite chips, slag, silica, sand or pumice. Generally in this operation the work is packed tight and the barrel nearly filled.

Rolling consists in rotating a barrel containing a load of work and abrasive so that the load rolls over and over upon itself in a continuous flowing motion. Rolling may be done in either horizontal closed barrels, or in open tilt barrels. In this case the load is lighter and much more free to move within itself or "roll" as the barrel rotates. Work may be rolled with any one of a large number of abrasives of varying particle size, sharpness, and hardness, such as ground slag, sand, silice, pumice, volcanic ash, emery, carborundum, alundum, Vienna lime, crocus, rouge, and others. The abrasive is generally finer in size than is used in tumbling.

Both tumbling and rolling may be done either dry or wet, depending upon the results sought. The amount of "bite" to the abrasive, and the resultant cut, is affected considerably by the amount of water present. The water may contain dissolved chemicals such as muriatic or oxalic acid, acid salts as sal ammoniac, or cyanide, to aid in scale removal.

Ball burnishing is a method for putting a high finish or lustrous surface on metal parts, by rolling them in a revolving barrel with polished hardened steel balls (or some modification of these) and some lubricant. In tumbling and rolling, metal is removed from the surface. In ball burnishing it is not. The continuous rolling pressure and rubbing action of the heavy load of balls flowing over the metal surfaces of the work, peens and smooths out minute surface inequalities to produce the luster characteristic of an even reflecting surface. In some cases with small parts, such as buttons and rivets, the work can act as a self-burnishing load. Surface irregularities are cold worked or flowed to a more even plane. They are not cut down. Ball burnishing can be successful only on a surface properly prepared for this final finishing operation.

Tumbling might be compared to snagging or grinding, rolling is analogous to polishing or "cutting down," and burnishing corresponds to buffing. Tumbling removes sand and "skin" and scale and fins from castings, and scale from forgings. Rolling removes flash and burrs, wire edges, pits, rough spots, scale and rust, and cuts down a metal surface to an even and uniform condition. Both processes, unfortunately, also remove corners and "round-off" edges. Barrel burnishing puts a lustrous finish on a clean and smooth, but dull metal surface.

Tumbling—Foundries use a "rattler" for removing sand, rough "skin," and fins from castings. Scale and rust have long been removed by tumbling in acid, the mechanical action greatly aiding the pickling effect.

Modern tumbling equipment removes dust and dirt by exhausted air circulation and dust filters, and automatically self-loads and discharges the work as well as separates the work from the stars, sawdust and other materials.

Tumbling is the least expensive method of cleaning castings. It is claimed tumbling increases the strength of castings as the peening action during tumbling evens the surface and neutralizes internal strains. On some classes of work this has the same effect as annealing. Liberal use of stars or jacks is essential to quick and thorough cleaning to reach every pocket and corner of the castings and produce an even finish.

Barrel Rolling Operations—Rolling is done in open tilt barrels or in horizontal closed barrels. Rolling is a cutting-down operation. Depending upon time and

*Technical Director, Magnus Chemical Co., Garwood, N. J.

abrasive the cut may be light or heavy. It is applicable to such objects as will form a rolling load in a slowly rotating barrel. Generally, this means small parts, and ones which will not entangle, nest, or interlock, which are not so thin in any cross section as to become bent, and do not require the holding of sharp edges or corners. In some cases it is possible to have a little extra metal at edges or points subject to the greatest cutting down effect, to make this method acceptable. Hollow or drilled pieces from which the rolling abrasive cannot be readily rinsed, are not suitable. Generally this process is not used for pieces having a dimension much over 6 in. An exception is long-straight work, such as curtain rods, tools, and handles, which can be rolled in a horizontal barrel in such a way that their long axes are always parallel.

The tilt barrel designed for rolling small parts has an open top and is hence readily loaded and discharged. It can be inclined at different angles for varying effect.

The rolling action increases in intensity as the axis of revolution is lowered toward the horizontal. Speed of rotation varies between 20 and 60 r.p.m. and is usually better nearer the lower figure. It should in each case be suited to the requirements of the work. The speed should never be so high as to cause the work to "throw" or move in other than a gentle rolling motion. The barrel should be loaded so as to be from 40-50% full. An advantage of the open tilt barrel is that the operator can watch the progress of the work and avoid waste of time or damage to work by over rolling.

Types of Barrel Construction—Barrels are made of wood, rubber, and most of the metals, and in a number of shapes, both round and polygonal, and with "angle-cornered" and "round-cornered" bases. These different shapes provide different rolling action. The polygonal form gives the more effective rolling carrying the load farther up the side of the barrel and allowing it to roll at a steeper slope. Barrels may be left smooth inside or fitted with cleats, fins, steps, or similar device to effect more complete movement of work in the load. The individual pieces in the load should not only roll over and over, but should rotate in more than one plane, and move back and forth slowly in direction parallel to the axis of the barrel.

Wooden barrels are used for rolling comparatively light articles either wet or dry and particularly articles of nonferrous metals such as brass and nickel silver. They are not suited to withstand the wear of rolling rough or heavy articles in sand or other coarse abrasives.

The metal of construction should be such as to avoid galvanic action with load.

Cast barrels are used for either wet or dry tumbling or rough work involving the use of abrasives as coarse sand and gravel, and on finer work requiring fine pumice or emery.

Barrels of nonferrous metal are used for tumbling articles in certain acids which would corrode iron, and for rolling high grade brass articles which might become discolored by rubbing against cast iron.

Sheet metal barrels are used to tumble heavy articles which have sharp corners that might chip out a cast barrel and rapidly wear it away.

It is usual to set up the barrels with a water pipe arranged to run into the open head. When washing and rinsing in the barrel before rolling, or in rinsing solutions after rolling, a piece of hose connected to the water line is run to the bottom of the barrel. A running, rinse then displaces the solution by overflowing.

The work is usually discharged by tilting the barrel so that the load slides into a sieve-topped box, which serves to separate work from jacks, balls, or abrasive. Stout sieve caps on metal frames which lock tight into the head of the barrel are sometimes used. In this case the barrel is lowered and run in this position for a few minutes, allowing separation of work and rolling medium. the work being temporarily retained in the barrel.

Horizontal Barrels—The horizontal type of barrel is used for larger articles, or those with one long dimension. These roll more evenly in the horizontal barrel, giving more uniform cutting down and polishing. In the tilt barrel such parts would roll end over end and produce too much action on the end faces or corners. Horizontal barrels are also structurally better suited for large and heavy loads. The horizontal barrel is more generally used for "rough work"—grinding and smoothing up—and the tilt barrel for light finishing.

Horizontal barrels with the axis of the barrel a little out of line with the axis of rotation are used to give the most effective motion to the load.

Horizontal barrels are made with one or multiple compartments. They are usually of metal, often cast iron, although other metals may be used to meet special requirements. They may be lined with wood for rolling soft or easily discolored metals. Barrels should be designed to balance and run without jerks.

When work is wet tumbled in closed barrels, the barrels must be vented every few hours as dangerously high gas pressure builds up. Finely divided metal reacts with water, forming hydrogen gas, and the frictional heat generated by the mechanical working of the load builds up the pressure.

The open ended horizontal barrel is a quite different form. It is able to handle large loads and has been developed to a high degree for automatic operation. They are made to be self loading, and by means of spiral fins on the inside surface, are self discharging when the rotation is reversed. Some have a device for separating work from stars, balls, or slugs, and automatically returning the tumbling agent to the barrel.

Abrasives and Time of Rolling—Many abrasives are commonly used. Particle size, hardness, and sharpness are factors affecting the time required for rolling. Those commonly used are slag, cinders, sea sand, sharp sand, or builders' sand, pumice, limestone, and granite chips, broken glass, silex, emery, alundum, and carborundum. Pumice is a sharp but light and soft abrasive mostly used on brass and soft metals and for finish smoothing. Hard metals require hard, quick cutting abrasives such as the last three mentioned.

To give a more uniform action, to add weight, or to carry the abrasive with a rubbing motion into depressions or corners, an auxiliary load is often added, such as wood blocks, jacks, slugs, punchings, steel balls, or steel wool.

Where the surface of the work is soft, or where a brightening action is desired rather than a cutting down, milder or finer abrasives are used. Silica, chalk, lime, crocus, polyroth, and rouge, are suitable. Leather scrap or meal, felt, and hardwood (maple, boxwood, or *lignum-vitae*) sawdust are also used, usually dry, and sometimes with fine abrasive mixed with them. Sawdust is used to follow an abrasive roll to scour fine abrasive from the metal surface. Greater cutting action is obtained in the wet process. The amount of water present has a great effect upon the process. For maximum action, the amount should be just sufficient to make a wet paste or mud. If too dry the abrasive will stick to and coat the work and barrel interior, preventing the desired action. If too much water is present, the abrasive particles are largely at the bottom of the load and do not work evenly through the rolling mass.

Water evaporates during rolling and must be replaced or the abrasive will pack and ball up. To the water may be added chemicals. Dilute sulphuric or muriatic acid, or ammonium chloride aid in removing scale. Alkali and cyanide in small amounts are often added in rolling steel to improve the color. Cream of tartar or cyanide improves the color of copper alloys. Soap solutions are not used in cutting down or polishing operations, but later in the burnishing.

Proper barrel speed should carry the load of work and abrasive up the side of the barrel to approximately three-fourths of its inside diameter. The mass should then have a slope which causes the top of the load to fall over and roll backward upon itself.

Oil is also used for rolling with sharp abrasives; kerosene is often used with emery.

Dry rolling, using sawdust, is used in preference to wet rolling for brightening up screw machine products. Fine sawdust should be used to avoid as much as possible the clogging of threads and slots. The dry roll gives a better color in the allowable time and has less injurious effect upon the threads. If sufficient sawdust is used (several times the volume of the work load) to keep the screws or bolts well spaced apart, and away from the barrel surface, they may be rolled up to 2 hr. without appreciable dulling of thread edges. This is sufficient to give a high finish. If the work has any oil upon it, a short sawdust roll of about 15 min. should be given to clean, and the sawdust then changed. It is not possible to bring the work out entirely free from sawdust, but in some cases this is not essential.

To get "high finishes" that is, smooth, even, and bright surfaces, a long rolling is required. Starting with a coarse abrasive, this is gradually broken down so that as rolling proceeds, the cut becomes finer and finer.

The length of time required obviously depends upon the quality of surface desired, and upon the condition, shape and hardness of the metal surface. The softer a metal the faster it is cut down.

Average times would be: Brass and bronze castings rolled 10-15 hr.; malleable iron castings 30-40 hr.; grey iron castings 70-80-hr. For stampings, or automatic screw machine parts, the necessary time varies greatly (from 1-100 hr.), depending upon the quality of the stock and the extent of die marks, scoring, or rough edges, brought from the machine operations. Ordinarily in preparing hot rolled and pickled stock for ball burnishing, the parts are rolled for about 48 hr. Forging scale is often removed to an extent of 80-90% by a roll of a few hours. A very much longer time would be required to completely remove it.

Often before barrel rolling and burnishing much time is saved and a net economy effected by giving one wheel operation. Sprues, parting fins, or any gross surface irregularities should always be removed by an abrasive wheel or belt. Deep scratches or score marks are also best polished out on a wheel before rolling.

Barrel Burnishing—The purpose of barrel burnishing is to develop high luster on parts otherwise unfinishable (because of size or shape), or to provide this finish at a lower cost than possible with hand labor. It allows the finishing of small parts in bulk. It can replace buffing upon a wheel in many cases. Barrel burnishing may be used as a preliminary to electroplating and as a finishing process afterward.

Burnishing has no cutting or abrading action; it must avoid these. In burnishing, rubbing pressure flattens and spreads all minute surface irregularities to a perfectly even surface. This action also tends to eliminate porosity in plated surfaces.

Burnishing will not remove visible surface irregularities, scratches, or pits. It will not improve color. These conditions must be cared for by treatment preceding the burnishing operation. (See Barrel Rolling.)

In barrel burnishing, the rubbing action which produces the burnishing may be between pieces of the work itself (self-burnishing), or between hardened steel balls (ball burnishing), or other suitable forms as cones, slugs, or pins, and the work. The rubbing pressure varies with the weight and depth of the load, and is influenced by the speed of rotation. A lubricant solution to prevent metal to metal contact in the rubbing is used. This prevents abrasion of the metal surface and heating of the load, and promotes the development of the high luster which is the object of the process.

The general rule for the ratio between amount of work and amount of burnishing agent seems to be to use about two volumes of burnishing agent (balls, et cetera) to one of work. On some work 1-1 suffices. The proper ratio is influenced by the type of barrel, and whether it is run full or only partially full, and by the form of the work. It is largely the weight of the burnishing mass which provides the pressure. It is essential that there be ample balls to completely space off and surround each piece of work. Hollow or recessed work requires a larger proportion than solid articles. Stampings require more balls than castings or forgings. One certain rule is that it is better to use too many balls than too few.

Work floating or riding upon the burnishing mass can obviously be under no pressure and hence does not burnish. Work cannot float upon the balls if there is no free space left above the burnishing load.

Burnishing Agent—Round steel balls are the most satisfactory burnishing agent generally because they can be hardened and they best supply the fundamental combination of half rubbing and half rolling action. Pressure is a necessary factor in burnishing. Too much pressure, however, between ball and work might result in grooving, or rubbing off metal. When undue pressure, because of some resistance in the load, might occur, grooving is avoided by the natural tendency of the ball to roll. The balls need not be perfectly spherical but they must be hard, smooth, and too tough to fracture.

A ball will not burnish in corners and angles. It cannot enter an angle, slot or indentation smaller than its own diameter. In such cases, or where the surface

of the work is figured, the use of other shaped pieces is required. Slugs or diagonals or burnishing steels, cones, ball-cones, fin-balls, pins or "oats" as illustrated in Fig. 1 burnish into angles, corners or grooves not reached by balls. These forms are generally used in admixtures with balls. Too high a ratio of pins or "oats" may cause a stippling effect upon flat work. When balls are mentioned, it should be understood to mean either balls, some of the modified forms, or mixtures of these.

The size unit of burnishing agent is important. Small balls obviously provide more contacts with the work. While the small balls provide more contacts, they give lighter pressure. Large balls are less expensive, and least readily lost while handling. It is common practice to mix two sizes of balls.

With drilled, slotted, or recessed work it is advisable to choose balls larger than the holes or slots into which they might otherwise wedge.

On soft metals small balls are necessary to avoid too much rubbing pressure. Balls $\frac{1}{8}$, $\frac{1}{4}$, and $\frac{1}{2}$ in. in dia. are the sizes most commonly used.

Much time and work are expended to make the surface of burnishing balls

Fig. 1.—Burnishing balls, slugs, pins, and ball cones for burnishing operations (Hartford Steel Ball Co.).

work or it may be an accretion of the sticky insoluble lime soaps formed from the burnishing soap and the small amount of hardness usually present in all waters. Balls should be kept clean and bright at all times. Dirty balls are usually cleaned by rolling them with a warm solution of sodium cyanide of about 1 oz. per gal. concentration. They may also be cleaned by rolling with metal cleaner and thoroughly rinsing afterward.

Surfaces to Be Burnished—Preparatory to burnishing, the metal surface must be put in proper condition to attain the final quality of finish desired. It must be remembered that burnishing will not remove metal or take out surface blemishes. It is absolutely impossible to secure good results without a good surface to begin with; if not naturally present, it must be prepared by rolling with abrasive.

In addition to being smooth, the work must be clean of all dirt, rust, scale, or tarnish.

Burnishing will improve luster. It will not improve color. Brass and copper, bronze and nickel-silver, are often bright dipped and thoroughly rinsed before burnishing to give good color. Annealed drawn brass, or brass which through handling or standing around has taken on an uneven color, or perhaps actual tarnish, must be either bright or cyanide dipped. A dip commonly used is made up by pouring 3 volumes of sulphuric acid (1.84 sp.gr.) into 3 volumes of water. Then add 1 volume nitric acid (sp.gr. 1.4).

A pinch of salt (sodium chloride) or about 1% of hydrochloric acid (conc.)

mirror smooth. Successful burnishing with them depends upon their being kept this way. Steel ordinarily rusts easily, and balls with surfaces so roughened or pitted are seriously impaired. Steel does not rust when kept immersed in a solution of pH 9.5 or greater. A dilute soap solution, or a dilute solution of soda or alkali will have a pH of at least 9.5, and hence steel balls kept under such solutions are protected.

Balls pick up dirt or scum and become dull or even black. This may be dirt brought in on the

added daily makes the dip more effective. The temperature of the dip should not rise over 95°F. Lampblack is usually added to bright dips sufficient to form a thin covering film on the surface.

Aluminum and particularly aluminum die castings are generally first dipped in hot dilute (about 3-4% conc.) caustic soda solution for 5-10 sec., rinsed, and then bright dipped in a solution made by mixing 3 volumes nitric acid (sp.gr. 1.4) and 1 volume hydrofluoric acid (48%) used at room temperature. A container for this solution is a matter of some difficulty. A lead lined vessel, painted inside with a mixture of 1 part beeswax and 4 parts paraffin is recommended.

Hydrochloric acid (20° Baumé or sp.gr. 1.16) is used for brightening steel or iron and for removing rust. Acid ammonium citrate in dilute warm solution will remove light rust without roughening a polished steel surface.

Sometimes, after burnishing a short time a dark scum will be noticeable on the solution covering the load. If this occurs, the solution should be run out, the load rinsed, and fresh water and burnishing lubricant added.

The load of work and balls is usually just covered with water. The burnishing lubricant is added and the barrel closed and set in rotation. Of burnishing soap, sufficient should be used to build and hold a heavy cushion of suds in the barrel throughout the run.

Importance of Hardness—The harder the metal surface of the work the higher the finish it will take. Many small steel parts which are finished by ball burnishing are hardened especially for this reason. It takes longer to develop luster on the hardened metal but higher quality and more permanent results are obtainable.

Soft metals, however, can be ball burnished to a good luster. By using small balls and low speeds to avoid undue pressure, even die castings can be brought to a high finish. Brass and soft nickel plate and nickel-silver can be given a beautiful luster. Die castings on account of being soft must be ball burnished with a relatively small burnishing ball, at a low speed, and with more than the ordinary amount of lubrication.

Ball burnishing is of course just as applicable to a plated surface as to a solid metal. A hard plate will take on a better luster than a soft electrodeposit.

Zinc and aluminum die castings can usually be brought to a good finish in about 60 min. Sometimes overburnishing is detrimental. A 60 min. burnishing period is also usually sufficient for nickel or for brass.

On steel burnishing time varies greatly depending upon the quality of the surface, the result desired, and above all on the hardness of the steel. It ranges from 15 min. to 100 hr. or more.

Chromium plate is harder than nickel plate and under similar conditions should be burnished about twice as long.

Chromium solutions have what is known as a "bright range." Sometimes parts will be dark or "burned" in some spots due to too high local current density and will be dull in other parts, due to too low local current density. Ball burnishing evens up the finish by giving a more uniform brightness in such cases.

Speed and Time for Burnishing—The speed of rotation should be adapted to the nature of the work. It also depends upon the diameter of the barrel. The smaller the diameter of the barrel the faster the allowable speed. The faster the rotation the more movement in the load and the greater the number of burnishing rubs. Or on soft metals too great pressure may develop causing deformation of the surface. Small or regularly shaped pieces can be run faster than large or irregularly shaped pieces. Pieces with edges or sharp corners must be run slowly. If the work shows scratches, dents, or peen marks the speed must be reduced.

Racking and Work Holding Barrel—With pieces which scratch or dent each other, or pieces with large smooth areas which must be free from rubbing marks, racking is essential. The application of a framework into which the parts can be locked by clips, or by clamping the frame together after loading is obvious. Or, some shapes can be slid upon rods with spacers between the parts. The racks are designed to just slip into an open ended barrel.

Sometimes it is important to keep parts from nesting together. This can also be done by racking. Threads, as on studs, where only the head need be finished, can

be protected by slipping over them tight fitting short pieces of elastic rubber tubing.

Unloading the Barrel—After the burnishing has proceeded for sufficient time to give the required luster the solution is run off and the load of balls and work thoroughly rinsed with clean water. Any soap film left on the work will dim the luster. With brass, or similar alloy, residual traces of soap cause rapid tarnish and loss of color. It is then necessary to separate the balls from the work and dry the latter. The customary procedure is to dump the load upon a riddle or sieve of mesh suitable for the balls to fall through to a tray or box. The upper box is arranged to slide on cleats. After the balls are riddled through its screen bottom, the upper box is removed to carry the work to a sawdust or hot air drier. The bottom box can be arranged with a bottom sloping toward the front. The balls collecting there can be returned to the barrel by a portable loading machine.

Work removed from the barrel is commonly dried by tumbling, or rubbing with clean, dry sawdust; maple or boxwood sawdust is preferred. It is sometimes passed through a hot air dryer. The latter is used for those parts which retain sawdust, as split or tubular rivets, threaded or slotted screw machine products.

Sawdust is the best drying medium where it can be used. It acts as a cushion between pieces and prevents scratching or marring. Good hardwood sawdust only is suitable. It must be dry. Moist sawdust clings to the work and is apt to leave water marks. The sawdust is kept dry by circulation through a fanning mill or by having it in a box or bin with a steam coil in the bottom. Cob meal (ground corn cobs) is an excellent alternative for sawdust.

Burnishing Lubricants—Many kinds of material have been used for burnishing solutions. Soap, soap bark, blackstrap molasses, stale beer, alkalis, alkaline cleaners, cyanide, and cream of tartar are the most important. First and foremost among these is soap; at least in amount and extent of use.

Soaps may be made "neutral," "acid," or "alkaline," depending upon whether alkali base and fatty acid are present in exact chemical equivalents or not. Small percentages of free alkali, or of free fatty acid greatly influence the properties of soap solutions. Commercial soaps often contain added filler or builder (alkaline salts or silicate), rosin, or solvents. Depending upon the method of saponification, glycerine may be either removed from or left in the soap.

Soaps in commerce vary greatly. They vary greatly in solubility, gelling power, lathering, rinsibility, alkalinity, and viscosity. The difference in properties are important in barrel burnishing.

High titer soaps give the best lubrication and burnishing action. They may not be used where good rinsing is a controlling factor; or in a tumbling machine where their solutions would gel. Lower titer soda soaps are best where rinsing is difficult because of nature of the work.

For nickel, brass or other copper alloys, or aluminum, a neutral soap is required. A small amount of borax or bicarbonate of soda (which are less alkaline than soap) or of cream of tartar is used with the soap. On aluminum the proper nonalkaline soap means the difference between success and complete failure.

For steel, the presence of free alkali is desirable. The use of cyanide with soap upon steel is also desirable, as it increases the speed of burnishing and keeps the color white and free from a dull or leaden appearance.

The use of rosined soaps, or those containing silicate, should be avoided.

Where burnishing is done on a large scale, it is convenient to have a soap solution made up in a tank or barrel, and add a measure of the liquid soap to the burnishing barrel instead of throwing in dry soap. In this way it gets to work immediately the barrel is started. Where other ingredients are used with soap, this is particularly desirable.

The soap or soap mixture should be added in amount sufficient to build and maintain a heavy suds in the barrel throughout the burnishing period. More than this is wasteful. The volume of soap solution should be just sufficient to cover the load.

Soap bark is often used for burnishing brass and other copper alloys which are sensitive to alkaline tarnishing. Soap bark and cream of tartar, or "tartar substitute," is a favorite combination.

A good formula on steel is made by dissolving 30 lb. high titer burnishing soap in 50 gal. hot water together with 15 lb. alkali (as trisodium phosphate or soda ash) and a couple of "eggs" of sodium cyanide. This sets to a jelly soap. Use about 1 quart to average load.

Dry burnishing is sometimes done where for some particular reason the use of the wet method must be avoided. It generally takes several times as long. Steel is dry burnished with cocoa butter and lime, or sometimes chip soap and rouge; nickel with leather meal and rouge; aluminum with leather meal and whiting; zinc die castings with boric acid crystals.

After burnishing brass and rinsing thoroughly, a dilute solution of bichromate is sometimes used to hold the color. The work is then again thoroughly rinsed and dried.

Burnishing Barrels—The design and construction of burnishing barrels has developed in different directions. There are several different types all in common use. Barrels may be single or in tandem. They may be single, double, or triple compartment barrels, or a single barrel may be built with a number of different pockets, each a separate sector of the barrel. In these a number of different small lots of work can be run at one time without mixing. The barrel may rotate evenly about its axis, or with some designs, it may rotate eccentric to its axis, giving the load a combined rotational and oscillating movement.

Barrels are commonly made with cast shells. Cast iron is not good to roll articles against as it has a tendency to deaden color. Hence, these barrels are wood lined, with hard maple. It is important that a wood lined barrel be kept wet and the cover on when not in use, to prevent drying out and shrinkage of the lining. For a similar reason, wood barrels made for dry rolling should not be run wet. They will swell and buckle, or burst the bands. Wood being somewhat porous, it is essential that wood barrels be kept scrupulously clean. After use with any solution containing chemicals they should be thoroughly rinsed several times. Strongly alkaline solutions rapidly disintegrate wood linings.

Burnishing barrels are also made of cast steel without wood lining, or of iron with welded sheet steel linings. For burnishing iron or steel articles, these are more durable and provide increased burnishing area but are not recommended for brass, die castings, or similar alloys. Brass lined barrels have been used for ball burnishing brass with excellent results.

Ball Buffing—By using small amounts of very fine abrasive, such as rouge, or Vienna lime, in the burnishing barrel, the effect of buffing is obtained.

Small pellets of leather (about the size of a marble) are coated in glue, rolled in abrasive and when dry, used for dry barrel buffing on intricately shaped pieces which could not be finished on a wheel.

Slushing Compounds

By W. C. Winning*

Oils and grease-like materials employed for coating metal surfaces to protect them against atmospheric corrosion are often termed "slushing compounds". Their ability to afford complete and lasting protection is dependent upon the maintenance of a continuous and unbroken oily film which excludes air and moisture from the metal. Unlike paints and varnishes, which after application are converted by profound chemical changes to tough, durable solids, most slushing compounds are chemically inert and rely for permanence upon physical properties alone.

Slushing agents are far cheaper than paints, frequently provide superior protection, lend themselves to quick application and removal, and are of special merit where only temporary protection is sought.

Fundamental Principles—If an object has been slushed with a light mineral oil, as by dipping, it will be observed that the coating tends to thin out as the oil flows down any inclined surface. Finally the point is reached where flow ceases, yet a thin oil film remains which adheres most tenaciously to the surface of the metal. While this coating in its original form appears to afford complete protection, it gradually evaporates and when rained on, washes away to leave the metal exposed, whereupon corrosion sets in.

When higher viscosity oils are employed the thinning proceeds more slowly, the ultimate films are thicker, evaporation is retarded because of the lesser volatility of the viscous oils, and the coatings, being tougher, are more resistant to the washing action of rain. Consequently, oils of high viscosity give protection far superior to those more fluid.

The protective action of mineral oils is sometimes reinforced by additional agents which because of their chemical affinity for the metal, their low volatility, or special water resistance, add to the permanence of the oil film. An alternative procedure for enhancing the serviceability of mineral oils, lies in converting them to greases by the addition of soaps or waxes. Such greases (or slushes) if properly prepared, have no tendency to flow from inclined surfaces and consequently a protective film may be maintained of sufficient thickness to resist most, or all, weathering influences.

Methods of Application—Oils may be applied by dipping, brushing, or spraying. Often they are advantageously applied hot, the consequent lower viscosity making more uniform and thinner coating possible with resulting saving in oil consumption. Wax base slushes are best heated to above their melting point for application and may then be treated like oils. Many soap type greases, however, do not thin until heated to quite high temperatures and are then seriously impaired in quality. These are therefore usually brushed or smeared on.

As an alternative to heating, highly viscous materials may be cut back with light solvents which evaporate after application.

Before applying slushing compounds to any object, the latter should be scrupulously cleaned of all corrosive materials. Solder fluxes and grinding compounds may of themselves set up corrosion or discoloration of the metal below the slushing oil film. Finger prints may carry corrosive compounds. Perhaps the best way of removing such materials as are water soluble, is washing with an emulsion of a suitable soluble cutting oil. A thin but tenacious oil film is left on the metal surface and affords good protection until reenforced by the slushing compound subsequently applied. In some cases the soluble oil itself is sufficient protection.

Materials Used in Slushing—While in general the user of slushing compounds will best be served if he asks the assistance of the compounder, it is well for him to have a sufficient knowledge of available slushing materials to know what to seek.

Mineral Oils—These, because of their general availability and low cost, properly form the base of most slushing preparations. They may be obtained in viscosities ranging from that of water to that of asphalt and in color from white to yellow to red to black.

Those of a viscosity under 200 sec. Saybolt at 100°F. should never be employed alone unless exceptionally little protection is required. In the 200-500 viscosity

*Standard Oil Development Co., New York.

zone are the oils which give fair protection, need no heating for application, and will burn clean in heat treating operations. With oils of higher viscosity, especially of 1000 sec. and over, far more permanent protection may be obtained, though even the most viscous oils, when used alone, do not give complete protection against severe outdoor weathering.

Fatty Oils—Lard, olive, and sperm oils used by themselves give excellent protection against the atmosphere but slowly oxidize to become gummy and generate acids which, particularly on copper, brass, bronze, and solder, may seriously corrode the metal. Used in concentrations of 20% or under in mineral oils they are less objectionable, but the improvement over straight mineral oil is not sufficient to warrant their use except in special cases.

Semidrying oils such as corn and cottonseed, and drying oils such as fish and linseed, should only be used under exceptional circumstances where their gumming and acid forming tendencies are considered desirable rather than harmful.

Fats and Waxes—The addition of paraffin wax to an oil causes it to solidify. The more wax used the higher the solidification temperature or melting point. Petrolatum gives more uniform products and the resultant films are tougher and more adhesive than those obtained with paraffin wax.

Light colored petrolatums are low in melting point and adhesiveness. They should therefore be used undiluted when color requirements demand their employment. Crude heavy petrolatums give permanent films and they may be cut back with 50-80% of mineral oil to give good slushes. Mixes high in petrolatum require heating before application. High viscosity cut backs should be used where maximum durability is needed.

Fats such as lard and tallow usually offer no advantages over petrolatum and frequently introduce corrosion.

Lanolin (wool grease)—Wool grease, commonly termed degreas when crude and lanolin when purified, is considered to be free of all tendency to form corrosive acids and gums, and is characterized by a high resistance to the washing action of water and is difficult to wipe off.

The increase in free fatty acid content of lanolin does not affect its protective qualities to the same extent as does the same increase in acidity found in other products when exposed to light and air. Generally, the lanolin is carried in a light petroleum solvent which upon evaporation deposits a thin coat of lanolin on the parts to be protected. It may also be used with mineral oils, alone, or hardened with resins and applied in solution, emulsion, or hot.

It has been found that the lanolin not removed from the sheet in cleaning will generally be incorporated with most lacquer and japans, whereas a mineral oil slush is not picked up by the lacquer or japans so it will not adhere to the sheet.

Rubber, Rosin and Asphalt—These may be added to oil to obtain increased viscosity. However, the use of soaps, petrolatums, and wool grease generally gives so much better results that they are rarely employed as thickeners.

Used together in solvent solutions these agents are sometimes applied like paints and give a relatively nonsticky, tough film suitable for the protection of small machine parts to be stored in bins or under similar mild conditions. Washing with kerosene instantly removes the film when the part is to be used.

Greases—The addition of soda or lime soaps converts oils to greases. The resulting products are usually excellent for slushing purposes and can be turned out covering a wide range of characteristics. In color they resemble the base oil used and in consistency they may be had light enough for dipping, though in general the heavier grades, which must be applied by hand, are to be preferred.

Corrosion Inhibitors—Oil soluble chromates, particularly sodium dichromate, are sometimes added to slushes. They are claimed to be particularly effective in preventing "underfilm corrosion". Whether their use is beneficial or actually harmful has been a source of much controversy and it can only be pointed out here that some users of slushes find them satisfactory; whereas others manage nicely without them.

Such materials as red lead, blue lead, and zinc chromate, also occasionally find their way into slushing compositions. (See note A on next page.)

Typical Applications—The following examples may assist in visualizing the applicability of slushing compounds. In each case cited there may of course be alternative procedures which will give as good or better results.

Ball Bearings and Races—After careful cleaning to remove grinding compound, pack with an amber petrolatum and wrap in paper.

Small Auto Parts for Service Departments—Treat as above or coat with asphalt paint by dipping.

Razor Steel to Be Heat Treated—Dip in 50/50 mixture of 500 viscosity pale mineral oil and amber petrolatum.

Cold Rolled Auto Sheet—Same as above or coat with solution of lanolin.

Freshly Machined Car Wheel Journals, Roll Necks—Smear a handful of grease on machined surface before removing from lathe.

Exposed Gears and Similar Parts on Logging Machinery—Smear with heavy black grease which will also serve as lubricant.

Removal of Slushing Compounds—Frequently the part slushed will in subsequent service require lubrication. In this case a slushing agent should be chosen which itself either will prove a satisfactory lubricant or will not objectionably contaminate the lubricant to be used. Mineral oils and petrolatum mixtures are to be preferred since fatty oils and rosin often have a deleterious effect on lubricating oil. Greases may be used wherever grease lubrication would be permissible, otherwise they had better be avoided. When these precepts are followed no particular effort need be made to remove the slushing material.

Surfaces subsequently to be painted must be carefully cleaned since with most slushing agents any traces remaining prevent the proper adhesion and setting of the paint. This is even more true when lacquer is to be used. Washing with hot soap and water is perhaps the most effective for removing slushing agents. It must be followed by thorough rinsing, quick drying, and often buffing to remove any light rust formed during drying.

In some cases the agent can be burned off in a suitable oven and the metal then buffed. Frequently solvents are used to effect removal of the oil or slush but this procedure is always costly and often hazardous.

Slushing compounds employed for most other purposes are little affected by subsequent uses to which the article is to be put. They need merely be wiped from the surface with a rag or waste. Where a particularly heavy coating material has been used a kerosene soaked swab is more efficient.

Precautions—Where inflammable volatile solvents are employed they constitute not only a fire hazard but the vapors are themselves harmful when inhaled. The noninflammable chlorinated solvents are even more objectionable in this respect and should only be used where good ventilation is available.

Note A—Recently a mixture of 10% aluminum stearate, 10-13% butanol, 5-6% triethanolamine, and the remainder lard oil has been recommended by the Ethyl Gasoline Corp. for the protection of the interior of airplane engine cylinders when the engine is to remain idle for some time, especially in tropical regions. The composition has the ability to neutralize residual corrosive materials as well as protect against the customary atmospheric corrosion. This and similar mixtures may well find use where related specialized corrosion problems are likely to arise as in the protection of rifles, artillery, etc., which after firing are difficult to free of residual corrosive materials.

Composite Steels

By T. S. Fitch*

Definition—"A Composite Steel shall consist of two or more components of which the smallest shall comprise at least 3% of the total mass."

Characteristics—The advantage of using a composite steel may be any one of, or a combination of, the following: (a) Hard working area with a tough backing. (b) Reduction of original cost where one of the components is expensive, and cost of production is not too great. (c) When the finished article must be hardened the backing may be drilled after hardening. Likewise, some straightening is possible after hardening if warpage has taken place. (d) Improved shock resistance. (e) Surface protection against corrosion and oxidation. (f) Inasmuch as each component has a period of vibration of its own, there is a dampening effect upon the vibration of the composite steel as a whole therefore lessening chattering. (g) Special physical properties as a result of combining dissimilar materials, such as thermostatic effect in lead-in wire for electric bulbs to match thermal expansion of glass.

The chief disadvantage of composite steels, both in production and fabrication, is warpage. This may be due to differing expansion characteristics or to an unbalanced arrangement of the components so that the stresses do not offset one another. In many instances the quality of the weld is extremely important, and not all of the methods which are to be described necessarily result in satisfactory welds; the application for which the composite material is to be used may determine the best method to utilize.

Fig. 1-6 indicate an average example of various types, and each sketch is accompanied by a list of typical applications.

Blacksmith or Forge Weld Method—The "blacksmith's weld" or "forge weld" is undoubtedly the oldest method for producing composite steels and it is also the simplest, but it is definitely limited to carbon steels or lightly alloyed steels. Any steel containing more than approximately 0.50% of tungsten, chromium, nickel or cobalt will yield uncertain results. Steels containing up to 1% of vanadium, manganese, silicon or molybdenum can be forge welded with a fair degree of success. The principle is the application of pressure to two or more pieces in contact at elevated temperatures (usually 2000°F. or higher). It is customary to employ borax or any other convenient flux, to absorb the iron oxide and thus leave relatively clean welding surfaces. The skill of the blacksmith is of considerable importance; if the pieces (particularly the steel) are left in the fire too long there is so much oxide formed that the borax will not absorb enough of it and a weak weld will result. Likewise, if insufficient borax is used too much oxide may remain.

The Casting Process—This is probably the oldest method which has been used for tonnage production. As its name implies, a composite ingot is produced by pouring one metal onto or about another. There are many variations in the technique so only the general methods will be mentioned:

(a) The earliest application was probably for the making of "soft center" plow shares. Molten high carbon steel is cast about a previously positioned iron insert so that the iron comprises about $\frac{1}{4}$ of the cross section and is located centrally. It is important that the insert be reasonably clean; it is usually pickled just prior to casting. It is also important that the insert be completely enveloped by the molten metal because it may be readily shown that no weld is actually produced in the ingot when one metal is cast around a relatively cold insert. If there is space for air to penetrate between the insert and the cast metal prior to further working an excessive amount of oxide forms on the surface of the insert and the cast metal. With carbon steels it is possible to produce a bond even if the insert is not entirely enveloped, but the weld will not be so good.

Casting mild steel around cold alloy inserts (particularly stainless steel) is being done commercially in this country. For a full description of the process see the article entitled "Stainless Clad Steels" on p. 1162. It is especially important that the inserts be completely enveloped by the cast steel and that special precaution be taken to ensure that the inserts shall be as clean as possible when the mild steel is cast.

(b) Various attempts have been made, with varying results, at casting metal

*Manager, Composite Steel Div., Jessop Steel Co., Washington, Pa. Prepared for the Subcommittee on Metallic Coatings; H. S. Rawdon, general chairman.

onto or around an insert that has been heated previous to casting. When the inserts are heated in gas, coal or oil fired furnaces without some surface protection a poor weld results when alloy inserts are involved.

(c) In England, particularly, successful composite steels have been produced by casting one steel into a mold divided by a removable partition, then removing the partition and quickly casting the second steel into the mold. Since both metals are in the fluid or nearly-fluid condition good welds may be produced.

Fig. 6—Jailbar (b); stoker bars (a) or (b); special structurals (a) or (b); dies (a); punches (a); pivots (a).

(d) By increasing the surface of the insert it is possible to improve the bonded condition of a composite steel. To accomplish this increase in the surface area, serrations are cut in the insert as shown in Fig. 7.

(e) It is also possible to make a satisfactory composite casting where the strain on the weld is not great by "keying" the insert into the backing. Fig. 8 shows how an insert might be cut so that it would be mechanically held in the casting.

(f) One of the newest methods is to electropickle the insert to be absolutely certain of removing all oxide, then move it (wet) into a plating bath and deposit

thereon a protective coating. This coating is usually iron because it is easy to weld onto, produces no zone of weakness as would copper, and also because iron has a high melting point. The electroplated insert is then placed in a mold and the molten metal is cast thereabout as already described. Excellent welds are obtained by this method.

(g) In another method, a coating is placed on the side of the mold wall prior to casting, which coating is composed chiefly of ferroalloy of the desired parent

metal plus certain chemicals so that controlled cladding ($\frac{1}{16}$ – $\frac{1}{2}$ in.) results when the molten metal is cast into the mold. This method can also be adapted so that cladding can be placed on previously cast or forged articles.

Generally speaking, it may be said that the casting method is convenient for tonnage work; it permits of producing sections which are irregular in themselves or in which the inserts are irregular; and it is generally the least costly.

The Cementation Process—This process utilizes cements which are in many cases complicated combinations in which the basic constituents are iron filings, silicomanganese, ferrosilicon, nickel and borax. Some of these cements are so

effective that it is merely necessary to squeeze the excess cement out and, after it has hardened, a good bond is evidenced. On large sections a heavy press is advisable, but on small tools (such as tool bits for lathes) the components may be squeezed and held until cold with a pair of tongs. The producers of these cements require that temperatures in the vicinity of 2300° be employed and they also recommend that the surfaces be machined prior to cementation.

One of the latest refinements of this general process has been applied to producing nonmetallic substances with metallic claddings; for example, wallboard with a thin cladding of stainless steel is made by putting a special cement on the non-metallic surface, placing the stainless sheet thereon, then putting them through rolls to bond the two components together.

Fusion Welding Processes—Many articles which come within the definition of composite steels, as it has been used throughout this discussion, are and can be produced by the fusion welding processes. For a discussion of Facing Surfacing, see page 1172.

(a) When the components are small enough in size the penetration of the welding heat may be sufficient to produce a strong joint between the components. For example, in the making of composite die sections it may be desirable to weld a piece of steel 1 x 1 in. onto a section of mild steel $1\frac{1}{2} \times 2\frac{1}{4}$ in. as indicated in Fig. 9. The welds are made along the lines A-B and C-D and, with proper control of the arc, good fusion may be effected to a depth of $\frac{1}{2}$ AC during each welding operation; thus the finished section will be completely fused throughout the entire weldable plane ABCD. When the strain on the joint is not to be excessive it may not be necessary that the entire plane be fused but this is a matter of trial and error.

(b) Electric resistance welding has been successfully adapted to the making of composite hack saw strips. Low voltage, high amperage current is conducted through rolls to the mild steel strip and the high speed steel strip, which are both held firmly together by the rolls as shown in Fig. 10. Likewise many other composite tools such as reamers, end mills and twist drills have been produced by resistance welding. Excellent welds may be effected in this manner but the method is generally confined to small sections—because of the abnormal cost on large sizes.

(c) For applications in which a cheap steel faced with a corrosion resisting, heat resisting or other expensive alloy surface is desired such composite steels are often produced by "spot welding" one to another. The result is a large number of welded spots surrounded by nonwelded areas so that such material is not as safely formed as a composite sheet or plate having a homogeneous welded condition. If the strain on the weld is not to be excessive composite plates thus produced will be satisfactory and the cost may be less.

The Assembly Process—This method involves the joining together of prefabricated bars or plates, then subsequently reworking the assembly to the desired finished form. For a complete description of this process see the article entitled "Stainless Clad Steels" on p. 1162. This method is advantageous in many cases because of its greater flexibility on small quantities as compared to any of the casting methods; also it is possible to control the relative proportions of the components more accurately. Generally speaking it is somewhat more costly than the casting process.

The article on "Stainless Clad Steels", as its title implies, deals only with the corrosion and heat resisting products but the methods described, particularly that method involving the electropickling and electroplating of a protective coating onto the insert or inserts, are equally adaptable to other steels.

Backings—Only recently has special consideration been given to the backing materials utilized in the production of composite steels. The problem is complicated by conflicting requirements, especially in cases where the insert is so placed that it tends to pull the bar out of shape. An important consideration is the desired physical characteristics of the backing material in the finished article; for example, a composite hacksaw steel should have as tough a backing component as possible without becoming too hard during the hardening of the blade; whereas, a composite stainless plate should usually have a soft back that may be readily formed. For any application involving heat treatment it would be ideal to have a backing with the same coefficient of expansion as the alloy in order to eliminate warpage. From the producer's point of view it would be ideal if the two metals had equal rates of elongation so that the composite product could be worked similarly to solid steels. Further, the value of the backing material must necessarily be considered,

because the additional cost of making composite steel has to be offset in some manner, else the selling price will be too high.

(a) The most often used backing analysis is S.A.E. 1020, which is relatively inexpensive, is easily obtained, is readily formed even after hardening, and is comparatively simple to weld. On the other hand, if the backing steel is preferred to be fairly tough then S.A.E. 1020 is not the best type; its coefficient of expansion differs appreciably from that of those alloys customarily used for inserts, which means difficulty in any heating or cooling operation; its rate of elongation is more rapid than the usual insert alloys; and it has a tendency toward enlarged grains when the composite product must be annealed after working. In spite of these drawbacks it has been and probably will continue to be the usual commercial backing for most applications.

(b) In cases where the comparative coefficients of expansion are most important a silicomolybdenum steel (carbon 0.10%, manganese 0.20%, silicon 1.50%, molybdenum 0.50%) has proven satisfactory. Also S.A.E. 2340 has given good results. These coefficients of expansion are more nearly equivalent to tool steels, particularly high speed steels, than any other relatively inexpensive steels so far tried.

(c) For applications such as chipper knives when the knife must have a good tough backing component to absorb severe shocks, the following analysis has proven excellent: C 0.28-0.34; Mn 0.45-0.65; Si 0.35-0.55; S and P 0.020 Max.; Cr 0.85-0.95; V 0.20-0.25.

(d) For applications such as hacksaw blades where it is desirable to produce some hardening effect in the backing steel the following analysis has proven satisfactory: C 0.42-0.50; Mn 0.50-0.65; Si 0.20-0.40; S and P 0.020 Max.; Ni 1.25-1.45; and Cr 0.50-0.65. This results, after proper hardening, in a backing that has springiness and superior abrasion resistance. It is somewhat harder to weld properly, but this can be circumvented by the proper choice and manipulation of method.

These analyses should not be considered as hard and fast rules because the carbon content is most important and alloys of various combinations may be added to vary the physical properties.

Heat Treatment—The difficulties in the proper heat treatment of composite steels are dependent on where the insert or inserts are located, relative proportion of insert or inserts to backing component, relative analyses, and suitability of equipment. Considerable experience is usually necessary before fully satisfactory results are obtained, but fortunately a composite steel can usually be straightened somewhat after hardening and tempering.

(a) *Design*—The significance of the location of the insert or inserts is only important when the coefficients of expansion differ. If the tool steel and backing steel had the same expansion rate the warpage would be no worse than on a solid piece of either steel. When the insert is symmetrically placed within the mass of the composite cross section, there is no abnormal warpage because the deformational stresses offset one another; for example, a composite bar having a high carbon, high chromium alloy steel center uniformly surrounded with S.A.E. 1020 will not pull out of shape during heat treatment. When the insert is along one edge or entirely covering one flat surface the composite steel tends to bow; when the insert is in one corner the bar tends to be pulled out of shape in two directions so that this form is the most difficult to heat treat.

(b) *Relative Proportions*—The smaller the amount of tool steel as compared to the amount of backing the less the tendency will be toward warpage, which is obvious because the net deformational strength is directly proportional to the relative masses.

(c) *Relative Analyses*—The greater difference in the thermal properties of the component metals the greater will be the warpage effect in heat treatment. Inasmuch as the thermal properties are primarily determined by the analyses (also somewhat dependent on grain size) it is obvious the relative analyses are important.

(d) *Air Cooled*—Any composite steel composed of materials that can be cooled in air may be held straight in a press after it is removed from the furnace. In some cases, particularly where the insert is in one corner, a special die is made up for the press with a groove cut in the die so that the bar is sure to be straight lengthwise as well as on the flat.

Multiple Heat Treatment—Small composite sections may best be heat treated in pairs. About the maximum convenient size is $\frac{1}{2}$ x 6 in.; bars larger than this have too much distortion strength. The clamps would have to be so big to hold

them that handling would be inconvenient, and unless the clamps were carefully designed nonuniform heating might result. The intention of this multiple heat treating method is to so arrange the bars within the group that the stresses will offset one another. A typical example is shown in Fig. 11.

Presetting Method—This method requires considerable experience to learn just how much and in what direction to deform the bar prior to heat treatment so that the stresses during treatment will cause it to return to reasonable straightness. This method is not recommended when the insert comprises 40-60% of the total mass; for reasons sometimes seemingly unexplainable, one bar may distort one way and the next may distort the opposite; however, the distortion is usually not so great in these cases that the bar cannot be straightened after hardening and tempering.

The section should be so treated that, after tempering, the insert is convex. There need be no fear of straightening when the tool steel is under compression as the backing steel will elongate readily.

Annealing and Normalizing—The annealing or normalizing of composite steels should be considered from the producer's as well as the user's viewpoint. The simplest method of producing composite steels in which the insert mass is unsymmetrically arranged in the backing is to make the assembly or ingot double the finish form so that the stresses will at least partially offset one another; in this way they will have less trouble in the rolling and also less trouble in the annealing. Two typical forms are shown in Fig. 12. In annealing composite steels it is advisable to use the lowest temperature possible to avoid abnormal grain growth in the backing steel.

Testing—Composite steels, because of the presence of materials with dissimilar characteristics, present a peculiar and often difficult testing problem. Because of the numerous modifications in composite steels it is not practical to prescribe testing methods which will apply in all cases. The following comments are intended to be helpful in establishing and interpreting tests.

The simplest method for testing the welded condition is the bend test. For material clad on one side, it is recommended that one piece be bent with the cladding on the outside and a second piece with the cladding on the inside of the bend. In all cases it is wise to bend the piece back again because an improperly welded composite steel may bend one way without showing a fracture at the weld.

A more severe and reliable test of the welded condition may be made by pulling in a tensile testing machine a sample which has been prepared as shown in Fig. 13.

Welded flat tensile test specimens may be pulled satisfactorily and the results will usually be found reasonably accurate. In the case of round specimens which are machined from bar stock, the proportion of inserted material to backing material may be changed by the machining. Allowance should be made for this in evaluating the results.

The reliability of the various hardness testing methods depends chiefly upon the thickness of the piece to be tested. Samples $\frac{1}{8}$ in. thick or greater may be safely tested by Rockwell hardness testing devices or by any of the testing machines involving the drop and rebound principle such as the scleroscope. Samples lighter than 0.0625 in. are best tested on the drop and rebound principle machines. Actually the surest means is to grind or otherwise remove all the steel except that on which the hardness is wanted, then test the remainder.

In making cup tests on clad sheet and strip samples there will be some variation depending on the direction in which the cup is drawn; if the insert material is on the inside of the cup the draw tends to be better. The reason for this is that the soft backing material supports the harder insert material during the draw. Users who desire to determine the drawing properties should draw the material so that the stainless is on the same side as it will be in the finished product. Producers should indicate whether the cladding was on the inside or outside when reporting cup tests.

General—There are two methods in common use for indicating the location and extent of the insert in a composite steel: Acid etching and heat coloring. A warm 50% nitric acid solution will bring out the insert in approximately 30 sec.; the acid may be washed off with warm water; and lacquer, oil, or vaseline may then be put on the etched plane to protect it from subsequent corrosion. Heat coloring is often used when the insert is a tool steel or S.A.E. grade which can be turned straw or light blue by exposing the end to a temperature which does not adversely affect the structure of any of the components; it is also well in this case to protect

the colored plane with lacquer, oil, or vaseline. This latter method renders the insert more readily visible but is not so fast as the acid etch method.

When any machine work is done on a composite tool steel prior to heat treatment there is some hardening effect and thus a strain is set up. This strain is preferably relieved by normalizing before proceeding with the hardening. The warpage in the hardening and tempering may thus be reduced. This machine strain is not a serious factor on short sections (18 in. or less).

It is in the fabrication of composite steels that much of the advantage of these materials is found. For example, a tool steel composite bar may be 25% tool steel, and the balance soft steel which can be machined more quickly. Clad plates may be bent or formed more readily than solid material of the same analysis. Composite steels in which the inserted material is symmetrically arranged may be cold drawn faster.

The fusion welding of composite steels (this does not refer to the production of the composite steel itself) requires some special precautions: (a) Due to the tendency of the alloys in the insert to migrate into the unalloyed steel it is well to utilize welding rod having higher alloy contents than the insert steel; this tends to replenish any loss due to migration. (b) In electric arc welding the amperage should be maintained as low as efficient because excessive heat tends to admix the backing and insert steels. In the case of high alloy composite steels the carbon in the tool steel might be so reduced as to impair its desirable properties; also the backing steel might be embrittled at that point by carbon enrichment. (c) Thick composite plates ($\frac{1}{2}$ in. or more) should be bevelled away from the insert, then lay a small bead down along the abutting insert edges, turn the two over and fill in the back with whatever rod suits the conditions. (d) In the stainless clad steels it is well to add a stabilizing material such as titanium or columbium to the stainless analysis to avoid intergranular corrosion in subsequent welding; thus annealing can be eliminated after welding. (e) High grade shielded arc type electrodes or gas filler rods are recommended.

A skilled operator with suitable equipment can soon learn to weld composite steels in a wholly satisfactory manner.

For complete recommendations on sizes of rods, current intensities, and manipulation see page 220 on welding as well as other handbooks on fusion welding.

Stainless Clad Steels

(Sheets and Plates)

By L. C. Grimshaw*

Plates and sheets of mild steel faced with stainless steel have been produced commercially only within the last few years. The stainless steel layer usually constitutes 10-20% of the thickness of the plate or sheet, and either one or both sides may be coated. Such clad steels have been developed largely to reduce the cost of stainless plates, particularly for the many applications where only one side of the plate needs to be stainless.

Strength of Bond—The bond between the mild steel and its stainless "cladding" must be strong enough to withstand stresses incident to fabrication into the finished product. Stainless clad steels are produced that can be bent, spun into deep heads, and deep drawn without damage. Often the bond must be strong enough to withstand great stresses due to a difference of expansion between the stainless facing and the backing when heated and cooled repeatedly.

Methods of Bonding—Two clean pieces of mild steel will readily weld together if hammered while heated. With less facility, and usually with the aid of a flux, high carbon steel and mild steel can be similarly welded. Indeed, the first commercial use of laminated steel was probably such a combination used for turning plows, manufactured by John Lane in 1868.

Nickel and mild steel, and copper and mild steel, can be welded together by heat and pressure alone. High alloy steels cannot be successfully welded to mild steel by this method without considerable modification. They were first successfully welded by the method of "casting on," a method relatively old, and often referred to in technical publications at the turn of the century.

Stainless clad sheets and plates are successfully produced by the casting method. In one casting method, two cleaned stainless steel sheets are placed face to face with a separating material between them, and fusion welded together around their edges. These two sheets are then set upright in a mold, and mild steel is poured all around them. The composite ingot is hot rolled until it has received the desired amount of reduction, the edges of the rolled composite plate are trimmed off and it separates into two sheets, each clad on one face with stainless steel.

Temperature control during casting is important. Since there is oxide on the surface of the stainless steel insert in the ingot, no true weld can be made until this oxide has been broken up by elongation into small islands.

On account of the fusion weld required in their fabrication, it is important from an economic standpoint that the clad plates be made large in size. There is a limit to the amount of reduction that can be given by hot rolling before the separating material between the two stainless sheets fails to do its duty because of thinning out. The above method has been used to produce plates up to 1½ in. thick, but only of small size (1,500-2,000 lb.), and not thinner than 18 gage.

A different method for producing stainless clad plates by casting is said to be in successful use in England. Grooves are cut in opposite sides of a mold, in a position such that a spacer plate slid down in these grooves divides the mold in a ratio of about 3:1. Mild steel is cast into the larger space. After a short time the spacer plate is withdrawn, and stainless steel is cast into the remaining space. After cooling, two such ingots are surface ground, and their stainless faces placed face to face with separating material between them. "Straps" of mild steel are then fusion welded all around the sides to hold the two-high assembly together. The assembly is then heated and rolled, and separated into two clad plates by shearing off the edges.

It is not known to the writer how economical the above method is, but it would appear subject to all the limitations of the first casting method described.

A method, now in the early stages of development, appears to be especially suitable for the production of thick plates, in which the stainless steel may well be much less than 10% of the plate thickness. The stainless steel (usually 18-8) is deposited from electrodes onto the mild steel slab. This forms a good weld, and only enough hot rolling need be given to the slab to eliminate the cast structure of the stainless steel, to facilitate discovery and elimination of pin holes in the deposit, and to smooth the surface.

*Superintendent Duo Metals Div., Latrobe Electric Steel Co., Latrobe, Pa.
Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

In another method of bonding a thin sheet of iron is placed between the stainless and the mild steel, fusion welded around the edges to prevent scaling, heated and hot rolled. The thin sheet of iron is said to have a beneficial cushioning effect, and after a great deal of elongation by rolling a satisfactory weld can be made. Oxides are troublesome, and the results too uncertain for this method to be commercial. No matter how carefully stainless steel is cleaned, it becomes covered with an invisible oxide film as soon as it is exposed to air, and the oxide thus formed must be broken up by elongation during rolling into small islands before a weld can be made. It is undoubtedly easier to weld stainless steel to iron as the carbon content of the iron becomes lower. A variation of the above method would be to decarburize the surface of the mild steel before attempting to make the weld, and leave out the thin piece of sheet iron. A zone of pure iron in the weld is a zone of weakness, and should be reduced as much as possible.

A commercial method in growing use produces a good weld by removing the invisible oxide film on the stainless steel by anodic pickling in hydrochloric acid, and electrolytic iron is deposited upon a chemically clean surface. Iron plating is commenced while the stainless sheet is still wet with acid and free from oxide film. The iron plating is usually about 0.012 in. thick. Any kind of steel, so plated with electrolytic iron, will weld to mild steel if heated and rolled. Commercial production of stainless clad plates by this method is as follows: "Separating material" is placed between the juxtaposed faces of two sheets of stainless steel, and a watertight fusion weld made around the edges of the sheets. They are then pickled, the unit is iron plated, and placed between two thick plates of mild steel. This assembly is fusion welded together around the edges, both so as to hold it together as a unit during hot rolling and to exclude air that would scale the surfaces to be welded. It is heated and hot rolled. During the first pass a weld is made, and rolling is continued to produce plates of the desired size. The composite assembly behaves like mild steel, and may be cross rolled if necessary to increase the width. When the edges are trimmed off, the composite plate separates into two plates, each clad on one face with stainless steel.

If the stainless steel is an austenitic one (the 18-8 variety) it will expand a great deal more than the mild steel when it is heated for rolling, and so must be left free to expand laterally between the mild steel plates. Such an assembly ready for heating, rolling, and welding, is shown in Fig. 1. The expansion space is not necessary for martensitic or ferritic stainless irons.

During hot rolling, even with little reduction, an excellent, oxide free weld is made by this method. Diffusion soon eliminates the zone of electrolytic iron in the welded plate, this being less than 0.002 in. after 12:1 reduction of the two-high assembly. Diffusion is rapid while the plate is hot. Such plates may readily be spun into deep heads, or drawn.

Stainless clad plates are also successfully produced by iron plating stainless steel in the above manner, and casting mild steel around it. The surface of the stainless steel is as free from oxide as in the assembly method, and it is more satisfactory to cast mild steel against the iron plating than against the stainless steel itself.

In most of the above methods, whether by casting or assembling, it is common practice to prepare a "sandwich" with mild steel outside, stainless sheets inside, and separating material in the center, the "sandwich" being held together as a unit either by an excess of cast metal or by fusion welding the edges. The difference in the hot working properties and in expansion of the stainless and mild steel tends to produce curled plates. By rolling as a "sandwich," curling is prevented. Hot rolling of single clad sheets is not done unless the finished sheet can be straightened cold. Hot straightening is impracticable, as the straightened sheet again curls when cooling, particularly if clad with 18-8 stainless steel.

The separating material used in two-high assemblies is commonly a mixture of aluminum oxide and lacquer, applied like paint, so as to spread thinly and evenly over the steel surface. The lacquer dries in a short time, leaving the fine oxide powder adhering to the steel. Any inert oxide can be used, but silicate of soda should not be substituted for lacquer unless all moisture is driven off at a high heat prior to assembling for rolling.

Another commercial method of making stainless clad plates is to bond a stainless sheet to a mild steel plate by a special method of resistance welding. The electric current passes, not through the thickness of the mild steel plate, but from one spot on the stainless sheet through the surface of the mild steel to another spot on the stainless sheet only a short distance away. This method bonds by means of

a great number of resistance welds, placed closely together all over the sheet. Such a sheet is never rolled except in forming rolls. The bond, though discontinuous, is strong enough to withstand the stresses incident to fabricating into spun heads and heat treatment. By this method composite plates of any convenient size are provided, and thick plates are covered with a stainless steel protecting sheet of far less than 10% of the plate thickness. By this method many large tanks, cracking vessels, and chemical towers have been made.

Applications of Stainless Clad Steels—Stainless clad steel may be useful either because of lowered cost, improvement of physical properties, or both. Lowered cost appears obvious, but is difficult to attain. The stainless sheets used for cladding must have at least one perfect surface, and be flat. The mild steel plates must be flat if the assembly method is used.

The fusion welding of an assembly is expensive, and stainless rod must be used for weld A (Fig. 1). If the casting method is used, there is a waste by trimming.

Since clad plates are rolled in pairs one clad plate is always left over when only a single clad plate is desired.

However, many clad sheets are used because of the physical properties obtained. If the weld is a good one, cooking vessels such as are used in the varnish, canning, and soap industries are best made out of stainless clad steels. The inside of such vessels is required to be stainless, but a solid stainless steel vessel is subject to hot spots and low heat conductivity. The clad vessel combines the stainless surface with the excellent heat conductivity of mild steel.

It is often desired to use the 12 or 28% chromium ferritic stainless irons, but they are difficult to fusion weld. Ferritic stainless iron used as cladding on ductile mild steel solves these problems, and such clad steels are finding increasing uses.

Austenitic steels, such as 18-8, have a coefficient of expansion greater than that of mild steel, so for stainless clad plates used at elevated temperatures the bond must be good. The high quality of many commercial bonds is proved by the wide use of such material at elevated temperatures. If the fabrication of the vessel requires fusion welding, and intergranular corrosion is feared, an 18-8 that contains a stabilizing element is advisable, because a stabilizing heat treatment at 2000°F. is undesirable when applied to the mild steel backing, and would also probably warp the vessel.

Fig. 1—Assembly ready for heating, rolling, and welding.

Nickel and Nickel Alloy Clad Steel

By W. G. Theisinger* and F. P. Huston**

Nickel clad steels are composite materials made up of an open hearth steel base and a layer of pure nickel or an alloy of nickel-chromium bonded to it on one or both surfaces.

The composite plate is formed by pressure welding the clad material to the steel slab in a rolling mill at a temperature of about 2200°F. Thorough cleaning and protection of the bonding surfaces during heating insures an intimate bond between the cladding and the base plate. A reduction ratio ranging from 8:1-16:1 is generally used. A solid solution of nickel and iron is formed at the junction plane of the two metals.

The ratio of the cladding material to the base plate is usually expressed as a percentage of the total thickness of the composite plate. For example, a ½ in. plate clad 10% one side only, consists of about 0.45 in. of steel and about 0.05 in. of pure nickel and a ½ in. plate, with 20% cladding, consists of about 0.10 in. of pure nickel and 0.40 in. of steel. The same order of thicknesses of cladding are produced for plates clad both sides. It is the usual practice when cladding both sides to use an equal thickness of either nickel or the nickel-chromium alloy, although different thicknesses may be applied. Plates clad one side with nickel and one side the nickel alloy may be obtained for special purposes. Nickel clad steels are regularly supplied with standard claddings of 5, 10, 15 and 20% with flange quality steel of 55,000 psi., minimum tensile strength, as the standard basis metal.

The clad surface possesses the same chemical and physical properties as would a solid, hot rolled nickel plate. It is bonded uniformly to the steel and does not separate from it as a result of changes in temperature, pressure (vacuum), or deformation in forming. Nickel clad steel is suitable for any conditions for which pure nickel is suitable. The clad plate is produced in sizes and gages generally comparable to plates obtainable in carbon steel.

Properties of Pure Nickel for Cladding—The modulus of elasticity of commercially pure nickel is 29,000,000-30,000,000, which is essentially the same as for steel, and its hot working range is likewise similar to that of steel. Its coefficient of expansion is close to that of steel, and for all practical purposes they may be considered identical. The melting point of nickel is 1455°C. ± 1 and that of steel which varies somewhat with the composition is somewhat below the melting point of pure iron, 1535°C. ± 3 .

The fact that the modulus of elasticity of nickel is the same as that of steel is of importance in a composite material such as nickel clad steel plate and insures an equal distribution of stress across the section of the plate with no sudden change at the interface between nickel and steel.

Properties of Nickel Clad Steel—Results obtained on an 8 in. tensile test specimen of ½ in. thick nickel clad steel with 10% cladding are as follows:

	Tensile Strength, psi.	Yield Point, psi.	Elong., % in. 8 in.	Reduction Area, %
Clad	60,600	40,400	30.0	57.2
Plate	60,800	40,200	30.5	59.0

To determine the value of bond between the nickel and steel, a clad surface was placed at right angles with the striking face and with one blow of a power hammer a 1 in. cube, with one face clad 20%, was flattened cold to ¾ in. thickness without rupturing the bond. To test the strength of the bond under sudden changes of temperature, a 10% clad plate (18 x 9 x ½ in.) with stiffeners welded to the steel side was heated to 900°F. and quenched in water at room temperature. No separation of the nickel layer occurred after quenching 30 times.

Utilization of Nickel-Clad Steel—Cold bending, flanging, forming, beveling, and the like, can be readily carried out on nickel clad steel. Generally, and especially when shearing and punching the nickel side should be up so as to prevent damaging the surface and to throw the burr on the steel side.

*Welding and Metallurgical Engineer, Lukens Steel Co., Coatesville, Pa. **Development and Research Div., International Nickel Co., New York.

Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

Annealing—Annealed plate is required for severe cold working operations, such as in pressing heads and die work. To anneal, heat the plate to 1650-1750°F., hold at temperature from 1-3 min., and allow the plate to cool in the air.

A fuel of low sulphur content (not over 0.5%) should be used to prevent embrittlement of the nickel layer. A covering of lime on the nickel surface is helpful.

Heating—When heating nickel clad steel, either for annealing or for hot working, the plate is charged into the furnace which is at temperature. The atmosphere should be reducing and the flame should not strike the surface.

Hot Working—The hot working of nickel clad steel entails no unusual difficulties if the proper conditions for heating are maintained. No change need be made from usual steel practice as to temperatures, amount of work done on each heat, or the general methods used in performing the work.

Joining—Joining nickel clad steel plates and heads to form pressure vessels and tanks may be done by gas or electric welding, or riveting and caulk welding. With all methods, the nickel surface should be made continuous by welding all junctions in the nickel side of the joint with nickel filler metal. In general, the corrosion resistance of such welds is not inferior to that of the nickel surface.

Metallic arc welding is the method generally used. The plates are beveled as shown in Fig. 1, and the vessel is assembled by "tacking" on the steel side. The weld on the steel side is then made with a covered steel electrode, no change from standard practice for welding plain steel is required. A narrow groove on the nickel side is then chipped to a depth at which the chip no longer shows parting. The width and depth of the groove vary with the thickness of the cladding layer but should be kept to a minimum. The width is usually $\frac{1}{4}$ in. and should never exceed $\frac{3}{8}$ in., even in 1 in. plate. The welding on the nickel side is done with coated nickel electrodes. If two beads are required the slag should be completely removed from the surface of the first bead before the second is deposited. Butt welding is most commonly used but the lap, and the butt-and-strap joint are used also.

Carbon arc welding, on account of the slow speed possible, is only occasionally used for welding nickel clad steel but yields strong, dense welds of high ductility. Acetylene welding gives satisfactory joints in nickel clad steel and no change from regular procedure is needed in welding the steel side. However, in welding the nickel side it is important to maintain a slightly reducing flame. The intense flame that yields entirely satisfactory welds in steel gives brittle and spongy welds in nickel. Bare nickel, gas welding wire is used, without flux.

Nickel clad steel may be welded in all positions such as are encountered in erection work by any of the methods mentioned. In vertical welding it is advisable that the weld be started at the bottom and worked toward the top, rather than in the reverse direction.

Welds in nickel clad plate meet the requirements of the A.S.M.E. Boiler Code. Samples of plates welded as described above were stress relieved at 1150-1200°F. and gave the following results:

Tensile Tests of Welds

	Tensile Strength, psi.	Yield Point, psi.	Elong., % in 2 in.
Full section	65,300	40,700	25.0
Reduced section	59,800	40,300	22.2

Bend Tests

	Elong., % in 1 in.
Steel weld, outside surface.....	31.0
Nickel weld, outside surface....	37.0

Fig. 1—Beveled butt joints

Design—A continuous nickel surface should be maintained in the fabrication of pressure vessels and other equipment. Jackets are welded or riveted to clad vessels and any type of bottom outlet, either in solid nickel or nickel clad steel, may be attached. Forged, tapped welding flanges in solid nickel are used. Practically any formed shape obtainable in steel is obtainable also in the nickel clad material. The material responds readily to hot spinning, hot and cold pressing, and hand shaping in the production of various shapes.

Nickel-Chromium Clad Steel—This alloy contains 78-80% nickel, 12-14% chromium, and 6-8% iron, combines a high degree of resistance to corrosion with high strength and good working properties.

The manufacture of this nickel-chromium clad steel is similar to that of nickel clad steel. It can be fabricated with the same facility and the welding procedure is similar. In the welding of the clad surface of the plate, a covered electrode containing 80% nickel and 20% chromium is used. This insures deposited metal of approximately the same composition and corrosion resistance as the cladding.

Lead Coatings

By J. L. Bray*

Lead, and lead-rich alloys, as protective coatings on steel possess the advantage of being (1) malleable, (2) resistant to corrosion by most acid fumes, (3) low priced, (4) readily available; but also the disadvantages of being (1) difficult to apply, (2) not resistant to abrasion, (3) subject to the formation of pin holes and (4) cathodic to iron. The difficulty of coating iron and steel with lead results from the fact that the two metals are immiscible. The success of any lead coating process must depend upon either (1) mechanical adhesion of the coating to the base or (2) chemical adhesion through the medium of some other element such as tin, mercury, antimony or zinc.

Low Alloy Coatings—The application of coatings of the lead alloys of very low alloy content usually consists in coating the pickled or cleaned surface with another metal or an easily reduced salt followed by immersion in molten lead or by the addition of a small amount of a suitable metal to the molten lead, which metal will promote adherence to the steel base on immersion in the molten lead bath.

Lohman¹ devised a process for applying a coating of lead to steel involving cleaning in sulphuric acid followed by dipping in a bath composed of HCl, HgCl₂ and NH₄Cl. After drying, the piece was dipped in molten lead at a temperature of 950°F. Although coatings of superior merit could be produced, the process was not commercially successful on account of the serious hazards resulting from the use of mercury. Another experimental process,⁴ involving the use of antimony as a binding agent, consisted essentially in (a) immersion of the cleaned piece in a solution of SbCl₃ until the surface turned black, (b) washing, (c) treatment with ZnCl₂, (d) immersion in molten lead and (e) cooling in oil. A process somewhat similar, employing phosphorus in the form of tin phosphide as a binding agent, has been commercialized to a considerable extent. In a recently announced process by Garbutt and Butterfield,¹⁰ the article after cleaning with caustic and acid, is passed through an aqueous solution of ZnCl₂, then through a molten flux of NH₄F and glycerol and into the molten lead bath. It has not been commercialized as yet in this country.

Recently a process has been patented that involves the use of zinc as the bonding agent. The raw material is sheet steel or wire bearing a tight (thin) coating of zinc applied by hot dipping. After cleaning with a molten flux (NH₄Cl and ZnCl₂), the material is passed through a bath of molten lead-zinc alloy (645°F.), the zinc content of which must be kept at approximately 0.5% (the eutectic point). According to the most recent investigation,¹¹ zinc dissolves in lead in the solid state to the extent of 0.10% and the eutectic contains 0.5% zinc. In this eutectic, and in any slight excess of zinc (above 0.5%) in the lead, the zinc crystallizes in a needlelike form. The real binding agent of a lead-over-zinc coating is believed to be these needles of zinc which can attach themselves to the lead by solid solution of zinc in lead and to the sheet which has been previously coated with zinc.

High Alloy Coatings—The most familiar application of lead as a coating material for steel is terne plate (meaning "dull" as distinguished from a "bright tin" coating). The process of manufacture is similar to that employed for tin plate, so for a more detailed discussion of terne plate, see the article on tinning of steel, page 1106.

Pure Lead Coatings—No completely successful method of coating steel with pure lead by dipping has been developed. Lead clad articles with pure lead as the protective layer find many uses where apparatus for handling or storing corrosive liquids is concerned. They are usually made by flowing lead on a clean steel surface; by burning on a coating, which thus forms a continuous envelope over the entire surface; or by rolling on a layer of lead under considerable pressure. The surfaces are usually prepared by sand blasting. The bond is often a mechanical one.

Pure lead can also be deposited by electrolysis and this is the most satisfactory method for obtaining thin coatings. For certain small, irregularly shaped or special articles, lead plating is an important process. The lead thus deposited is very pure and has the superior corrosion resistance of a pure metal. Lead can be deposited from a variety of solutions, but the only ones which have found commercial application are the fluosilicate, fluoborate and perchlorate solutions. Electrolysis must

*School of Chemical and Metallurgical Engineering, Purdue University. Prepared for the Subcommittee on Metallic Coatings, H. M. Rawdon, General Chairman.

be carried out at fairly low current densities (5-20 amperes per sq. ft.) and much heavier coatings must be applied than is necessary in nickel, zinc and copper plating for the lead thus laid down is prone to "pinhole." When heavy coatings of pure lead are required it is usually better and cheaper to cast these from pure lead than attempt to put them on electrolytically.

Developments in coating steel with lead by the metal spraying process have been encouraging, lead being one of the metals which are easily applied by this method. See the article on sprayed metal coatings, page 1115.

Copper Sheets—While copper, if properly cleaned, can be coated with pure lead, an alloy containing a little tin is usually employed since the bond is better and the surface freer from pin holes. Such lead coated sheet copper shows a marked resistance to corrosion and is used as a roofing material and for other building material.

Utility of Lead Coatings—Lead in contact with iron and wet with an electrolyte functions as a cathode. Hence, a lead coating cannot protect iron electrolytically as zinc can. The value of lead coatings results from the high resistance of metallic lead against most acids. All lead coatings are porous. However, these can be more or less completely sealed up in the case of sheet by slight rolling of the sheet after the coating has been applied. The results of weathering tests of long duration (10 years) by the A.S.T.M. have strikingly demonstrated the relative merits of lead coatings in atmospheres of different characteristics. Lead coatings can be used to best advantage in an industrial atmosphere where the air is polluted with sulphurous gases. Perforations (pores) in the coating are soon sealed by the products of corrosion after which the corrosion is exceedingly slight. Companion specimens, however, in rural or marine atmospheres (A.S.T.M.) have immediately developed severe pin hole corrosion. Under conditions of high humidity, some blistering (separation of the two layers) has been observed.

A thin coating of lead assists in drawing and stamping operations on sheet steel by its lubricating action. It is for this reason that terne plate is so widely used in the fabrication of containers. The drawing of metals into tube, rod and wire form can be greatly expedited by using a thin surface layer of lead as in the drawing of some of the high alloy steels.

Copper Covered Steel Wire¹

By L. C. Whitney*

In many cases today, the engineering requirements on a material used demand a combination of properties that is not found in any single common metal or alloy. To develop these, composite materials are sometimes produced from metals whose combined characteristics meet the specifications. Copper covered steel wire, which is essentially a copper wire with a steel core, is an example of this. The copper exterior provides high electrical conductivity and good corrosion resistance, while the steel core allows the development of tensile strengths considerably above those attainable in hard drawn copper and bronze wires.

To produce this material, a round steel billet with properly prepared surfaces is preheated in a mold and molten copper is poured around it. After solidification, the composite billet is hot rolled to a rod. The composite rods are then heat treated or annealed and drawn into wire of the desired size.

The casting of molten copper around a heated steel billet with properly prepared surfaces produces a weld between the two metals. This weld withstands subsequent heatings, hot rolling, and cold drawing and the finished wire may be bent, twisted, or deformed without causing a separation of the two metals.

This composite wire is produced commercially in two grades which are based on the electrical conductivity of the material. They are the 30% and 40% grades, a designation which indicates the electrical conductivity as compared with that of a solid copper wire of the same cross sectional area. The electrical resistance measurements on each coil are maintained to the following limits:

Rated Conductivity	Max. Average Resistance for Entire Coil, Ohms per cir. mil-foot at 68°F.	Max. Resistance for Any Part of Coil, Ohms per cir. mil-foot at 68°F.
	35.26 26.45	39 18 28.59
30%		
40%		

In addition to the two conductivity grades, there are two grades based on the tensile strength of the wire. These are designated as "high strength" and "extra high strength" grades. Detailed information on the properties of individual wire sizes is given in Table I.

Table I
Properties of Copper Covered Steel Wire

*There is a slight difference between the weights of 30% and 40% conductivity wire. These figures represent the average for both materials.

*Chief Metallurgist, Copperweld Steel Co., Glassport, Pa. Prepared for the Subcommittee on Metallic Coatings, H. S. Rawdon, General Chairman.

¹Copper covered steel wire is sold under the trade name Copperweld.

To insure a uniform coating of copper of the desired thickness on the wire, all coils are tested with a magnetic testing device which measures accurately the copper thickness at any given point. By means of such equipment, it is possible to guarantee a minimum copper thickness at any point around the circumference of the wire of 10% of the wire radius on the 30% grade and 12.5% on the 40% grade.

Physical and electrical constants and specifications on copper covered wire are as follows:

Average weight of wire—8.15 g. per cu. cm. at 68°F. (equivalent values are 3.533 lb. per inch-foot and 0.002775 lb. per cir. mil-1000 ft.).

Coefficient of linear expansion—.0000072°F.

Temperature coefficient of electrical resistance for wire—.0021 per °F.

Modulus of elasticity—24,000,000.

Facing or Surfacing by Welding*

Facing or surfacing is a process of welding onto wearing parts (either old or new) a facing, edge, or point of a hard metal that is resistant to abrasion. Hard facing is a surfacing operation that has proved to be an easy and economical means of keeping equipment in good operating condition, without losing time for repair or replacement of worn parts. There are also soft surfacing operations, such as for example, applying bronze bearing metal.

Hard Facing—Hard facing was originally applied only on metal working dies, oil well drilling tools, and certain types of excavating equipment, but other applications were soon found in almost every field, so hard facing is now an important factor in the welding industry.

The major cost reducing features of hard facing may briefly be summed up as follows: 1. Longer life of equipment; 2. Fewer replacements with resultant savings in labor charges and lost production time; 3. Utilization of cheaper base metal for wearing parts; 4. Salvaging or reclaiming of worn parts; 5. Savings in power consumption; and 6. General increase in operating efficiency.

No single grade of hard facing material is satisfactory and most economical for all applications. For the requirements of hardness, toughness, shock resistance, corrosion resistance, and other qualities, various hard facing alloys of widely different compositions have been developed. These may be divided broadly into five groups.

Group 1—Alloy steels consisting of an iron base with less than 20% of alloying constituents are included in this group. Alloying constituents consist mainly of chromium, tungsten, manganese, silicon and carbon. These alloys are relatively low in cost and while not as hard as higher priced hard facing metals, they possess greater toughness and shock resistance. However, they have greater wear resistance than low carbon steels and some compare favorably with Hadfield's high manganese steel in this respect. Certain low priced and short lived alloys, such as low alloy cast irons, may be listed in this group, but they find only minor application as hard facing materials.

Group 2—This group consists of iron-base alloys with more than 20% of alloying constituents. Various amounts of chromium, tungsten, manganese, silicon, carbon, and sometimes cobalt, nickel and other elements are contained in these alloys. Naturally these hard metals are higher priced than those of lower alloy included in Group 1. However, they are harder, possess greater abrasion resistance and give longer service. As a rule they are not as shock resistant or tough as Group 1, but are particularly adapted for use as the final wear resisting surface, after the worn part is built up with high strength welding rod. Due to longer life of these metals, they frequently are more economical than cheaper metals.

Group 3—Nonferrous alloys of cobalt, chromium and tungsten make up this group. They are available in several different grades, all highly resistant to wear and corrosion, but having a spread in strength and toughness which makes them suitable for a wide range of hard facing applications. Because of their higher melting points these alloys have the property of red hardness, that is, they retain their original hardness practically unimpaired at elevated temperatures.

Group 4—The fourth group consists of the so-called diamond substitutes, the hardest and most wear resistant of all hard facing materials. Some of these are almost pure fused tungsten carbides, containing only fractional percentages of alloying constituents. Others contain 90-95% tungsten carbides, the remainder being cobalt, nickel, iron or similar elements. Other materials may contain boron compounds or tantalum carbide.

The alloys are added to impart toughness and impact strength to the tungsten carbides, the hardness of which, however, is slightly reduced as a result.

These diamond substitutes are furnished in the form of small castings, which are welded and imbedded into the cutting and wearing surfaces of oil well drilling bits and similar tools. Tungsten carbide inserts are not melted or damaged to any appreciable extent in the usual method of applying them by the oxy-acetylene process. The process of applying tungsten carbide shapes to wearing surfaces is

*Compiled and arranged by C. W. Obert, Sr., Union Carbide and Carbon Corp., from the pamphlet published by the International Acetylene Association entitled "Hard Facing by the Oxy-Acetylene Process". Reviewed and supplemented by several individuals in the electric arc welding industry.

known as "hard setting." After hard setting, the wearing surface usually is hard faced. This combination affords an excellent abrasion resisting surface with maximum cutting qualities at edges.

Group 5—Crushed tungsten carbides of various screen sizes comprise the fifth and last group. These are furnished packed in steel tubes of various diameters, fused to steel strips, or bonded with steel in the form of a composite rod. Both tubes and strips come in short lengths, which are applied like ordinary welding rods. Crushed tungsten carbides are also supplied loose, in granular or powdered form, to be sprinkled directly onto the wearing surface and melted into it. These types are more costly than the best of the hard facing alloys but this is more than offset by their much longer life on applications where wearing surfaces of composite nature are to be preferred.

Selection of Hard Facing Alloys—In order to select the correct hard facing material for any particular application, the user should first determine those factors which cause the deterioration of the wearing part. In general, the attack on the part will involve one or more of the following: Sliding or rolling friction, shock and impact, heat, and corrosion. Other factors, such as smoothness of the deposit desired, or, in handling sand, rock and gravel, the ability of the hard faced part to form an efficient digging tool, also affect the choice. The cost factor should also be considered, as a general rule, when two materials are equally suited, the material giving the longer life although more expensive will more than justify its greater first cost.

When the factors have been determined, the following table should serve as a fair guide in the selection of the proper material. The numbers refer to the five groups of materials described above.

Table I
Relative Characteristics of Hard Facing Deposits

Characteristic of Deposit	Group Number in Order of Preference
Cold hardness	4 5 2 3 1
Red hardness	4 5 3 2 1
Resistance to impact	1 2 3 5 4
Corrosion resistance	3 2 1 4 5
Smoothness of deposit	3 1 2 5 4
Ability to take high finish	3 2 1 4 5
Ability to penetrate (earth boring or penetrating tools).....	4 5 3 2 1
Thinness of deposited layer welding.....	3 2 1 5 4

Hard Facing Procedure—Although hard facing materials can be applied by any of the standard fusion welding methods, there are several factors which govern the choice of method for any particular application, such as: 1. Material to be faced; 2. Kind of hard facing material selected; 3. Size, shape and thickness of base material and deposited facing material; 4. Initial cost of equipment and facing material for each process; 5. Smoothness of deposits; 6. Overall cost; and 7. Quality and appearance of deposits.

Gas Welding—The oxy-acetylene blowpipe or torch allows close control over the operation and produces a smooth deposit. Particles of scale and foreign matter are easily eliminated by this method, and edges and corners may be readily formed. This is particularly important where it is later necessary to grind the hard facing to close tolerances. Other advantages are the elimination of any loss of expensive alloys by vaporization or spattering, close control of the oxidizing or reducing conditions of the atmosphere surrounding the molten metal, and more accurate control over the degree of penetration of hard facing alloy in the base metal. The latter is of importance especially with respect to the application of certain classes of hard facing materials, some of which should be puddled in, while others are flowed onto the base material at a "sweating" heat. The oxy-acetylene process offers the facilities for producing either condition at the will of the operator.

Metallic Arc Welding—In metallic arc welding, a metallic alloy rod constitutes both electrode and hard facing material. The electrode is usually flux coated instead of bare. The function of the coating is to stabilize the arc, control the melting rate of the electrode, protect the molten metal from contamination by atmospheric elements and in some cases add alloys to the deposit. While not as flexible as the gas welding process the resultant deposits are equal in quality.

With electric arc welding, experience has shown that in most cases, when the area to be surfaced is large, the most practical and efficient method of deposition is through the use of a weaving bead type of deposit, as distinguished from the straight bead type. This requires the deposition of a bead from $\frac{1}{4}$ -2 in. in width. A deposit of this type can be laid down of a uniform thickness and leave a smooth and regular surface.

Narrow beads are readily applied to corners and edges and for building up points. As it is natural that the edges of such deposits tend to be rounded, it is obvious that this can be offset by the use of double beads, or backing-up strips or jigs of graphite, carbon paste or copper.

Beading is sometimes used when covering large areas and under such conditions the beads should be staggered over the entire area and then tied in together. This method of deposition will give an even distribution of heat and will minimize the strain in cooling. For such applications preheating is generally unnecessary unless the surfaces to be covered are round, curved, concave or convex, in which case it is desirable to preheat. The thickness of the deposit depends, with electric arc welding, upon the heat used and the amount of build-up behind the crater. Normally this will range from $\frac{1}{4}$ - $\frac{5}{32}$ in. In some cases heavier deposit layers can be built up if the work can be placed on a slant of about 15° from the horizontal. On the other hand, thinner deposits can be laid down by moving the electrode over the work more rapidly.

The metallic arc welding process is particularly suitable for hard facing at low cost, thick base metals where exceptionally thin smooth deposits are not required. Distortion is also reduced when hard facing large steel castings and similar heavy parts by this process since the heat from the arc is well localized.

Atomic Hydrogen Arc Welding—In the atomic hydrogen arc welding process an alternating current arc between two tungsten electrodes in a stream of hydrogen gas furnishes the source of heat. The arc is surrounded by an envelope of hydrogen gas which protects the electrodes and work from oxidation. The arc is defined by a thin brilliant line which forms a loop under the influence of its own magnetic field and the streaming gas.

This process gives high quality of deposits plus all of the other advantages outlined for hard facing using the gas process. In addition, since the atomic hydrogen arc has a higher temperature and the heat is concentrated over a smaller area a higher deposition rate may be obtained. The initial cost for atomic hydrogen equipment is often more than offset by the speed and results obtained on many hard facing applications.

Materials Which Can Be Hard Faced—The following classification affords a ready means of determining what metals or alloys can or cannot be hard faced.

Medium and Low Carbon Steels—All carbon steels up to 0.50% carbon can be hard faced with perfect results in practically all instances. Such steels, especially in the 0.40-0.50% carbon range, are not only satisfactory from the viewpoint of the welding, but also have sufficient strength to stand up well under severe operating conditions.

High Carbon Steels—Steels containing above 0.50% carbon can be hard faced if reasonable precautions are taken to prevent the steel from cracking. It is often desirable to preheat such high carbon steels before hard surfacing. In most cases, heat treatment is necessary to remove hardness and brittleness from the base metal both before and after hard facing.

Low Alloy Steels—Hard facing alloys can be applied to low alloy steels in much the same manner as to plain carbon steels. Such material should be in the annealed condition before welding. In a few cases, depending upon the composition of the base metal, heat treatment is required after welding.

High Speed Steels—The hard facing of high speed steels is not generally recommended, because shrinkage cracks and strain checks render the hard faced piece valueless in a good many instances, regardless of heat treatment.

Stainless Steels—Stainless steels, including the high chromium steels and the 18-8 chromium-nickel steels can readily be hard faced if proper preheating and cooling procedures are followed. However, a knowledge of the physical properties of the particular type of stainless steel is necessary, otherwise difficulty may be experienced due to excessive strains, brittleness, or lessened corrosion resistance.

Manganese Steel (9½-14% Mn)—This class of steels can be surfaced to advantage by use of a rod that gives an austenitic, work hardening deposit. Man-

ganese steel should always be hard faced by the electric arc welding process, with care being taken to avoid overheating.

Gray Cast Iron—Cast iron can be hard faced easily, but the method of application is somewhat different from that for steel due to the lower melting point of the cast iron and the crust formation on the surface of the iron. Care should be taken not to develop localized overheating of the iron.

White Cast Iron—White or chilled iron can be easily hard faced in small parts; on larger parts heat treatment is sometimes necessary and a careful study of the design and location of chills is necessary, since preheating may soften some of the chilled areas.

Alloy Cast Irons—The same procedure can be used as for hard facing gray cast iron.

Monel Metal—Monel metal is easily hard faced.

Brass and Bronze—These copper-base alloys are difficult to hard face because of their low melting point. In rare instances, however, heavy sections which have been preheated to a red heat can be hard faced.

Copper and Copper Alloys—Because of its low melting point and high heat conductivity, copper is hard faced only with difficulty. Preheating is absolutely necessary.

Preparation of Work—All loose scale, dirt, rust, or other foreign substances should be removed from the areas to be hard faced, preferably by grinding or machining. If these facilities are not available, the surface may be cleaned with a file or wire brush, but this method often leaves scale or other foreign material which must later be floated out during the hard facing operation.

Where the hard facing material is to be applied to a groove, corner or recess, it is preferable to have all corners well rounded, otherwise overheating of the base metal may result. If but a small section of a part is to be hard faced, a suitable shallow recess or indentation to receive the hard facing metal may be prepared either mechanically or with the blowpipe or torch.

Preheating—The same general rules apply to preheating before hard facing as apply to most welding operations. Parts are always preheated in cases where the application of the hard facing alloy would otherwise cause them to warp or check, or where time and cost can be saved by preheating. Steels having over 0.40% carbon should usually be preheated. The optimum temperature of preheating is dependent upon the size and composition of the part, but usually it is between 700-1200°F. For certain classes of electric arc welding a preheat of from 350-450°F. is desirable.

It is generally unsatisfactory to hard face steels which are in a hardened state. If it is necessary or desirable to reharden the base material after the hard facing has been applied, it should be quenched in oil (water quenching is seldom used because it tends to crack many hard facing materials).

Fluxes—In the gas or atomic hydrogen welding process, fluxes are not ordinarily essential except in special instances. Sometimes a flux is of assistance where a second layer of hard facing is necessary, or to help remove scale and oxide from the base metal. This is especially true with cast iron. The principal advantage of a flux is that it floats on the molten puddle of deposited material, smoothing its surface and retarding the cooling action as well as protecting the metal from oxidation. In addition, a denser, harder deposit of superior microstructure is produced if a flux is used. No flux is required in shielded electric arc welding in addition to that processed on the electrode itself.

Thickness of Hard Facing Deposit—In the vast majority of cases, hard facing deposits range from $\frac{1}{8}$ - $\frac{1}{4}$ in. in thickness. The average is approximately $\frac{1}{8}$ in., but the proper thickness depends entirely upon the specific application. However, parts requiring a deposit thicker than $\frac{1}{4}$ in. are usually rebuilt, before hard facing, with one of the alloys of Group 1, or with the material of which the base metal is composed, to within $\frac{1}{8}$ - $\frac{1}{4}$ in. of the finished size. The final hard facing deposit is applied to a thickness allowing sufficient metal for grinding to finish size.

Hard Facing Steel—Group 1. Iron Base—Less than 20% Alloy—In applying hard facing welding rods of Group 1 to steel, a flame containing a slight excess of acetylene should be used, since a neutral flame may cause boiling and sometimes produces an unsatisfactory result. Penetration of the hard facing alloy in the base metal should be from 0- $\frac{1}{2}$ in., depending on the type of rod used. Some of these

materials are work hardening, and light peening is recommended, especially on large areas, both to harden the surface and to eliminate the danger of shrinkage cracks.

The hardness of deposited hard facing metals of this class depends largely in the case of gas welding upon the amount of acetylene used in the flame and upon the rate of cooling; a small excess of acetylene is usually necessary to prevent the rod from boiling. A much greater excess can be used if an exceptionally hard deposit is desired. In general, it may be said that the greater the excess of acetylene and the slower the rate of cooling the harder the deposit will be. A quenched deposit is not as hard as, but is tougher than, slowly cooled metal.

With electric arc welding, electrodes are available which will give a medium carbon alloy steel facing. With most of such electrodes the rod should be positive and the work negative. The welding current should be adjusted to give flat beads such as are generally produced with high currents, and the deposit should be made with a weaving motion where possible. For this class of work welding should be done in a flat position only.

Group 2. Iron Base—20-50% Alloy—It is generally recommended that alloys of this group be applied to steel by thorough amalgamation. In the case of gas welding, a neutral or slightly carburizing flame is generally used. To assure successful hard facing, melting of the base metal should actually take place; sweating is not advisable. Since the hardness and other physical properties of these alloys remain practically unchanged within a carbon content range of from 2-4%, penetration of the base metal has no marked effect on the quality of the deposit.

With electric arc welding electrodes are available that will produce a high carbon steel facing that is hard and cannot be machined unless annealed. For most of such electrodes the rod should be positive and the work negative. Wide or narrow beads can be deposited as desired. Each bead should be brushed thoroughly before depositing the next, and, in some cases, peening the completed bead will harden the deposit. Quenching in cool water will increase the surface hardening of some types of this group. For best results the work should be in as nearly a flat position as possible.

Group 3. Nonferrous Cobalt-Chromium-Tungsten Alloys—The nonferrous alloys should be applied, when possible, without penetration into the steel base metal. In this manner, it is possible to avoid dilution with iron of the base metal and thus preserve the red hardness and abrasion resisting properties of the alloys. With gas welding, the flame for hard facing with the nonferrous alloys must contain an excess of acetylene and should be adjusted so that the flare or outer cone denoting an excess of acetylene extends double the length of the inner cone. This amount of excess acetylene will make the surface of the steel base metal "sweat," allowing free spread of the hard facing metal without any stirring or agitation of the puddle by the rod.

A small area of the surface to be hard faced should be brought to a sweating temperature, and the end of the rod brought into the flame and allowed to melt and spread evenly over the sweating area. The hard facing material, when applied at the proper temperature, wets the base metal and spreads readily ahead in the flame as the flame brings the base metal to the sweating heat just ahead of the puddle. The rod should not be stirred or puddled. Additional alloy is spread in the desired direction by means of the welding flame.

It is usually possible and preferable to build up the coating to the desired thickness in one operation. As a general rule, no flux is necessary when the nonferrous alloys are applied to clean steel.

The alloys in this group can be applied by the metallic arc process either bare or flux coated, preferably coated. Reverse polarity is always used, making the rod positive and the work negative.

Group 4. Tungsten Carbide Inserts—Tungsten carbide inserts are now in almost universal use for hard setting oil well drilling tools. In general, the procedure involves, first, cutting grooves in the steel base metal by means of either an oxy-acetylene cutting blowpipe or a grinding wheel. The size and spacing of the inserts will vary with the type of drilling tool. The steel in one groove should be melted with an excess acetylene flame. One insert should then be picked up with the heated end of a high strength steel welding rod and partially submerged in the molten puddle. Finally the insert should be completely covered over with the steel welding rod. This operation is repeated until the desired number of inserts have been set. Maximum wear resistance is obtained when a final coating of hard facing alloys of Group 5 is deposited over the inserts.

Group 5. Crushed Tungsten Carbide with Steel Binder—These materials consist essentially of two types—composite and tube; both are applied in much the same manner. The operation should be performed with the oxy-acetylene process, using a flame containing a small excess of acetylene. The application should be made without penetrating as deeply into the base metal as in ordinary steel welding. A certain amount of stirring with the rod is necessary to obtain the most even distribution of the deposited metal. These rods do not flow as freely as most ordinary welding rods, due to the presence of the refractory tungsten carbide particles which are not melted during the application. It is best to avoid keeping the deposit molten for too long a period. The welding tip should be large enough to produce a flame which will supply the required amount of heat with the pressure low enough to avoid blowing the molten metal.

Hard Facing Cast Iron—Group 1. Iron Base—Less than 20% Alloy—In applying materials of this group to cast iron, a small area at a time should be heated with the blowpipe, and the surface crust broken with the end of the rod. A little puddling is usually necessary and a good flux is often helpful. Because of the low melting point of cast iron, considerable care should be taken when working up thin surfaces, edges, and corners. Other than this, hard facing cast iron with the materials of Group 1 is similar to hard facing steel.

Group 2. Iron Base—20-50% Alloy—These alloys are applied to cast iron in essentially the same manner as they are applied to steel.

Group 3. Nonferrous Cobalt-Chromium-Tungsten Alloys—These alloys when gas welding is used should be applied to cast iron with a little less acetylene in the flame than is used for steel. Since they do not flow as readily on cast iron as on steel, it is usually necessary to break the surface crust with the end of the rod. A cast iron welding flux is often helpful. It is usually best to weld in a thin coating first and then go over it again and build up to the desired thickness. These alloys have approximately the same melting point as cast iron, and care must be taken not to melt the base metal too deeply. If the cast iron is thin, it will prove advantageous to back it up with wet asbestos or carbon paste to avoid melting it.

Groups 4 and 5. Tungsten Carbide Inserts and Rods—These hard facing materials are rarely, if ever, applied to cast iron in practice. In those few instances where they are, the technique follows generally along the same lines as the procedure for their application to steel.

Cooling Procedure—Most satisfactory results are obtained after hard facing by the oxy-acetylene process if the part is cooled slowly to avoid setting up stresses in the deposited metal. A little more care is necessary than is employed when the base metal and welding rod are of the same composition. If no further heat treatment is necessary, the hard faced piece may be cooled under the blowpipe or torch, or can be cooled in dry lime, sand or other packing material. If, however, the piece is to be heat treated to improve the strength of the base metal, and to produce a finer and stronger grain structure, the hard faced piece should be heated and then either quenched in oil (seldom water) or normalized by cooling in air.

Finishing the Hard Faced Deposit—Groups 1 and 2. Iron Base Alloys—These hard facing materials may be shaped to a certain degree while they are in their plastic temperature range. When a deposit of one of these alloys is heated with the blowpipe to within 200-300°F. of its melting point, it may be scraped off in thin layers with an implement, such as an old file, until the deposit has been brought down to the required size and shape. Ordinarily, alloys of Groups 1 and 2 are difficult to machine. If they cannot be brought down to their finish dimensions exactly by "hot filing," as this procedure is known, grinding is necessary.

Group 3. Nonferrous Alloys—Most grades of the nonferrous hard facing materials are too hard to be machined or filed, but they can easily be finished by grinding. The wheel speed when grinding these alloys should not be less than 2,800 nor more than 4,200 surface f.p.m. Higher speeds or wheels that are too hard may cause grinding checks.

Groups 4 and 5. Tungsten Carbide Inserts and Rods—The best results in grinding parts hard faced with these materials will be obtained by using wheels designed for this particular work. Grinding wheel manufacturers should be consulted and their recommendations followed as to proper grade, grain and bond. All wheels should be kept sharp by frequent dressing to avoid glazing and checking of the hard faced surfaces.

Bond Between Hard Facing Material and Base Metal—The bond obtained between the hard facing material and the base metal is as strong and sometimes even stronger than the hard facing deposit itself. Naturally, those alloys which are puddled into the base metal form a good strong bond. Those alloys which are merely sweated to the base metal, actually form a bond which is stronger than the hard facing metal itself. If properly applied hard facing metals do not break away from the base metal at the bond.

On many hard facing applications, surface cracks are not detrimental since they usually run only through the deposited metal and stop at the base metal. If surface cracks are present and undesirable, they can sometimes be repaired by heating the metal adjacent to the crack to a red heat, then melting down into the bottom of the crack and allowing it to close in slowly, meanwhile adding a few more drops from the welding rod. The heat should be drawn slowly away from the hot spot into the body of the base metal to prevent quick cooling and subsequent cracking and the part should be cooled slowly in lime, sand, or mica.

Drawing-Out Rod—When rods smaller than $\frac{1}{4}$ in. dia. are required for application to small parts, it is possible and often desirable to "draw-out" $\frac{3}{8}$ or $\frac{1}{2}$ in. dia. hard facing welding rod to roughly $\frac{1}{4}$ or $\frac{3}{8}$ in. dia. This procedure applies primarily to those hard facing alloys of Group 3. Some operators prefer this practice while others prefer to buy the smaller diameter rods ready for use. Depending on individual shop conditions, including local costs for material and labor, one method or the other may be the more economical.

The actual drawing-out operation consists of melting one end of the large diameter rod with the usual excess acetylene flame. The first drop of molten rod is laid on a cold plate of carbon, graphite, iron or steel. With the welding flame playing steadily on the end of the rod and melting it, the rod is drawn away from the initial drop at a steady rate, leaving a thinner rod deposited on the plate. Angle iron or a grooved plate is generally preferred to a flat plate, since these give more uniform shape to the "drawn-out" rod. At the completion of the "drawing-out" operation the newly formed small rod is ready for use.

Jigs for Hard Facing—Many hard facing operations, both in production and repair, are facilitated by devices for holding the work and special jigs. Some operations which otherwise might not be practical, can be rapidly and efficiently accomplished through the use of auxiliary appliances. Profits derived from an operation are often greatly increased by the savings in labor, time and handling thus made possible. Several typical examples of jigs will suggest ways of facilitating the hard facing operation.

Several coal companies have found it much easier and faster to hard face undercutter bits when they are set up on a jig. Either a "merry-go-round" jig or a moving table may be employed to good advantage in this application. At one coal company which uses the former method, 450 bits are hard faced by one operator in an hour.

A well designed jig and nose plate help tremendously in obtaining properly shaped plowshares. With the aid of these accessories, a plowshare may be hard faced and its nose shaped in one operation. A further aid in plowshare work is the use of a jig designed to swivel as well as turn the share completely over. A share clamped in such a jig can be readily adjusted so that the area on which the welding operator is working is always level. Rotating jigs or chucks set at a convenient angle are a great aid in hard facing steam valves, dies, automotive valves and valve seat inserts and other small parts. Even simple rests on which the work can be placed are often helpful in allowing the welder to work in a comfortable position. Most jigs are home made affairs, adapted specifically to the jobs in question, and a little ingenuity on the part of the operator will aid him in turning out work more quickly and accurately with greater economy and convenience.

Rolls for the Metal Industry*

Rolls are used in the metal industry for reducing the cross section of plastic metal or changing its shape or both. As a rule, two rolls are used, running in opposite directions as shown in Fig. 1; the metal to be rolled, which will hereafter be called the bar, no matter what shape it has, passes between the rolls and is therefore reduced in cross section. In cross rolling, Fig. 2, such as used in the making of seamless tubing and straightening rounds, the rolls rotate in the same direction and set a piece of metal in rotation as it passes between them longitudinally.

Roll Parts—A complete roll with roll body, neck, and wobbler is shown in Fig. 3. The roll body or roll face is the working part in contact with the bar to be rolled. The roll neck is that part which lies in the bearing or journal box. The wobbler is that part which receives the torque from the outside source of power. Instead of wobblers, some rolls are equipped with universal joints, Fig. 4, which make contact on surfaces rather than lines or points and thereby minimize wear.

Roll Types and Arrangement in Roll Housing—"Blooming mill" rolls convert ingots into blooms.

Fig. 1—Illustration of rolling.

Fig. 2—Cross rolling.

Fig. 3—Complete roll with roll body, neck, and wobbler.

Fig. 4—Universal joints for rolls.

"Roughing" rolls are used in the early stages of reducing billets and blooms into various shapes.

"Intermediate" rolls, also known as "second roughing," "pony roughing" or "strand" rolls work on the bar after it comes from the roughing rolls.

"Leader" rolls are those preceding the finishing stand.

"Finishing" rolls or "planishing" rolls in the case of flat products are used to give the bar its final shape.

If only two rolls are used in a mill, the latter is called a two-high mill. If three rolls are used, (usually on top of each other) the mill is called three-high, and so on. Not all rolls are in contact with the material to be deformed. Some rolls act as stiffening or supporting rolls for smaller rolls which are in contact with the work. The latter are called working rolls while the former are called backing rolls. Fig. 5 shows the arrangement of rolls on three-high, four-high, and cluster mills.

Roll Requirements—Wear resistance is the first requirement for rolls since rapid wear of rolls impairs the surface or enlarges the section beyond the tolerance which can be used. Wear is caused by the relative motion between the bar and the roll surface. In all rolling there is relative motion between rolls and bar while roll and bar are pressed against each other at enormous pressures, which, in severe cases, reach several hundred thousand psi. Hardness is regarded as being a general guide to wear resistance, although it is not an infallible index. The roll hardness is usually determined by the Shore scleroscope because of the portability and fair reproducibility of results with this instrument. Hardness, and consequently wear resistance, of a roll is limited by the strength requirements since ductility and shock resistance decrease as the hardness increases.

*Prepared by the A.S.M. Subcommittee on Rolls. The membership of the subcommittee was as follows: S. C. Spalding, Chairman; F. H. Allison, Jr., W. P. Goss, E. H. Berges, A. L. Davis, W. Trinks, G. J. Buckner, J. R. Adams, J. T. Haight, Harry Jenter, V. M. Surerus, and F. C. T. Daniels.

Strength is necessary for the rolls to withstand fracture from bending, torsional, and shearing stresses to which they are subjected in operation. Sufficient strength for any application depends upon the chemical composition of the roll, the heat treatment, and the freedom from strains and internal defects. Initial strains are present to some extent in every roll. Size, thermal treatment, and casting conditions play an important part in these strains. Under service conditions, rolls which have high internal strains may rupture easily by uneven or rapid heating on the mill. This is particularly true of chilled iron rolls for sheet mills. Strength is necessary to resist spalling which frequently originates below the surface and progresses outward until the part breaks loose. Thus subsurface strength and hardness are required to keep spalling at a minimum.

Fig. 5—Arrangement of rolls on 3-high, 4-high, and cluster mills.

Bite is necessary for grabbing the metal and starting it through the roll. It depends partly upon the roughness of the roll surface. Bite is particularly important in taking large reductions, and in many blooming or roughing mills the surface roughness is artificially increased by ragging or knurling. This is done by cutting longitudinal grooves or welding ridges on the roll surface. Ragging must be applied with care or it will show in the finished bar. Where reductions are small as in the leader and finishing pass, a smoother roll can be used.

Surface perfection (quality) of the roll is necessary to obtain a good bar. In cold rolling where surface finish of the product is of great importance the roll surface must be ground to a high finish and be exceptionally free from defects. Only the highest hardness will preserve such a surface for a sufficiently long commercial operation. In hot rolling, the roll surface is subjected to fire cracking by alternate contact with the hot bar and the cooling water. Fire cracking is greater in the early passes where the hotter metal and larger reductions prevail. Both fire cracking and spalling which ruin the surface of the rolls are associated with roll strength.

The surface must be metallurgically correct. If the bar material has too great an affinity for the roll metal, it sticks to it and "loads" the roll. The solution to this problem is not always easy. Change of roll material helps in some cases; insertion of a lubricant between roll and bar helps in others; insertion of another metal between roll and bar has become necessary in a few cases.

Rigidity in a roll is essential to reduce the deflection or roll spring across the roll length. This is particularly important in rolling flat products such as plate, sheet, or strip. If the rolls spring, the edge of the section is wavy and thinner than the center. For a given diameter a steel roll is more rigid than a cast iron roll, but the hardness of the steel roll has no effect on its rigidity since deflections depend solely on the modulus of elasticity which is the same for hard steel and for soft steel. Leader and finishing rolls are made relatively short for the purpose of reducing roll spring and giving true finished dimensions. Crowning the roll will produce a flat section by making the diameter slightly larger at the center than at the ends, but crowning is a limited remedy since a given crown can be correct for only one thickness, hardness, and width of section.

Roll Size and Design—The size of a roll is specified by the diameter and the length in the order named, such as 24 x 48 in. Rolls for shapes are often designated by the nominal roll or pitch diameter, which equals the distance between the centers of the mill driving pinions. The diameter of the rolls is usually smaller than the pitch diameter because there must be room for the passing of the bar between them. Occasionally the roll diameter is larger than the pitch diameter when the rolls are new. Plain rolls, used for plates and strips, may sometimes be designated by the length of the roll body. Rolls of the smallest possible diameter are used as far as it is consistent with strength, bite, and rigidity because rolls of relatively larger diameter tend to spread the bar, cause greater roll pressure or separating force and use more power for a given reduction. Rolls are made as long as is consistent with safety against breaking by bending. The deeper grooves of grooved rolls are placed as far as possible from the center in a location where the bending moment is smaller.

For grooved rolls, a three to one ratio of body length to diameter is small while a four to one ratio is large. Smaller ratios, such as one and a half to one are used for leaders and finishers where deflection must be a minimum.

Fairly sharp limitations exist as to the largest size section that can be rolled on any mill because above a certain section the rolls do not bite, or break in bending, the wobblers twist off, the necks overheat, or the mill is stalled.

The sudden change of diameter from roll body to roll neck intensifies the bending and torsion stress at this location. The neck diameter should not be smaller than a certain safe fraction to the body diameter, which with plain bearings will average about the following:

Type of Mill	Ratio	Neck Diameter
		Body Diameter
Blooming mills		0.50-0.55
Sheet mills and tin mills.....		0.76-0.80
Strip mill, backing rolls.....		0.55-0.65
Strip mill, working rolls.....		0.60-0.65
Merchant bar mill.....		0.60-0.67
Plate mill, middle roll.....		0.60-0.70
Plate mill, top and bottom rolls.....		0.65-0.72
Structural mill		0.57-0.65
Continuous bar mill.....		0.70
Universal mill, vertical rolls.....		0.57
Cold rolling brass, heavy reduction.....		0.775
Cold rolling brass, finishing reduction		0.72-0.75

Misuse—Rolls can easily be broken or damaged by misuse. In hot rolling, the entering bar may be too cold or unevenly heated. Fire cracking usually occurs if the mill is stopped while the hot metal is between the rolls. The bar may run between the collars instead of entering the groove whereby the roll pressure becomes excessive. Strips or bars may by accident wrap around the roll, forming collars and inducing excessive stresses in the rolls. Lubrication may stop in cold rolling. Other events may occur on the mills which overstress the rolls and contribute to failure some time after the event. Among them are local heating, too rapid heating, too rapid cooling, bruises, and nonuniform cooling.

Forged Steel Rolls—There are special types of forged rolls made for specific applications but by far the greatest number are used for the cold rolling of metals and are of a generally standardized composition and finish. The average composition is as follows: C 0.85, Si 0.30, Mn 0.30, Cr 2.00, and Ni, V, or Mo may be added either singly or in combination.

Manufacture—Forged steel rolls are made from acid open hearth or electric furnace steel cast in ingot molds of suitable size and shape to afford the required reduction in forging to produce the necessary structure and grain refinement. After forging, the roll is put through suitable normalizing and annealing processes, after which it is rough machined to size and heat treated. The roll is then machined for hardening and hardened by heating to proper temperature and quenched in water or brine with special fixtures and devices to insure extreme hardness on the working face and prevent or retard hardening of necks, shoulders, fillets, and so forth. After hardening the roll is tempered to relieve strains and to obtain the desired hardness.

The roll is given a preliminary test for hardness. The customary test for hardness of rolls is the scleroscope. The next step is machining and grinding to finished dimensions and desired surface finish. Forged steel rolls are capable of a high surface finish. For special purposes a so-called "mirror finish" may be put on the rolls.

Application—This type of roll is used for cold rolling and for the finishing of thin metal where a high grade finish is desired. The hardness is varied with the service for which the roll is intended. For extreme hardness and fine finishing thin metals a hardness of greater than 95 scleroscope is usually used. For soft and thicker metal such as running down or semifinishing, a hardness of 80-90 scleroscope may be used. For heavy roughing and special purpose, hardnesses less than 80 scleroscope are used.

When forged rolls are used as backing-up rolls in 4-high mills, the scleroscopic hardness is dependent on sizes of roll and character of mill. For the small strip or band mill, the hardness should be 75-90 scleroscope. For the larger diameter forged backing-up rolls used in either hot or cold strip mills, the hardness should be within 55-80 in order to insure the maximum service possibilities. Forged rolls are applied

as backing-up rolls when high pressures are used and high strength required. Forged steel rolls of various hardnesses are used for many auxiliary purposes around mills, such as leveller rolls, pinch rolls, colling rolls, and carrier rolls.

The extremely hard rolls must be handled with great care and precautions taken in use to prevent them from being subjected to rapid changes in temperature. Before rolls are put into service they should be preheated to approximately rolling temperature preferably by means of heated water or low pressure steam in the bore. Preheating of rolls by means of a gas flame is dangerous and should never be used unless rolls are rotating. Rolls should never be warmed up by running them in contact with each other. Idling the rolls in contact with each other for any reason is dangerous. This practice may cause minute surface fractures that ultimately result in a spall. When not rolling, the rolls should be separated from each other and the cooling water immediately turned off whether they are rotating or not. Rapid and excessive heating of roll journals from defective bearings or improper lubrication, causing rapid local expansion or subsequent rapid contraction, will result in a broken or spalled roll or fire cracked journal.

Bruises on the faces of rolls frequently bring about spalling. Bruises often result from the ends of the strip being harder than the rest of the strip, from badly sheared ends, turned over or broken edges, pinches due to improper roll shape, or mill setup, nonuniform thickness of strip or sheets, passage of foreign material such as micrometers, or small spalls from backing-up rolls. Whenever a roll is bruised it should be ground until no trace of the spall remains after polishing and etching with a solution of ethyl alcohol containing 7% of nitric acid.

Forged steel rolls can be readily damaged by improper grinding. For roughing down and rough grinding coarse free-cutting wheels are essential. Fineness of grit for finish grinding and polishing depends on the finish required. The selection of the proper bond and hardness and adoption of correct roll and wheel speeds is necessary or injury to the face of the rolls will result. The grinding wheel manufacturer should be consulted when selecting the proper wheels for the condition that obtains in a shop.

Hardened steel rolls should be stored in a dry room kept at a reasonably constant temperature. They should be well slushed to prevent rusting. They are best supported on their journals. The forged steel roll makers customarily furnish instructions and precautions for the care and use of their rolls.

Cast Rolls—Cast rolls may be divided into two classes, (1) Cast iron rolls and (2) Cast steel rolls.

Cast Iron Rolls—Cast iron rolls in American practice are subdivided into three classifications: (a) chilled iron rolls with a definite chill; (b) chilled iron rolls with an indefinite chill; and (c) sand iron rolls.

(a) *Definite chilled iron rolls* (scleroscope hardness range 55-90) are those rolls having a definitely formed clear homogeneous chilled white iron surface of the body of the roll with a fairly sharp line of demarcation between the chilled surface and the gray iron central portion of the body. The depth of chill is measured as the distance between the finished diameter of the body and the depth at which the first graphitic specks appear. Below this there is an area consisting of a mixture of white and gray iron known as mottle, which gradually becomes more gray and more graphitic until it merges with the grey iron structure of the main part of the roll. The mottled area should be equal or somewhat less than that of the primary chill.

The definite chilled rolls are again subdivided into plain carbon and alloy rolls, the former having a hardness range from 55-72 scleroscope and were the standard rolls in use for both hot and cold rolling until the introduction of the alloy chilled roll. The average composition of carbon chilled rolls is as follows:

	C	Si, min.	Mn, max.	P, max.	S, max.
Soft	3.00	0.75	0.25	0.50	0.125
Hard	3.50	0.50	0.20	0.50	0.150

The alloy definite chilled rolls have a hardness range from 60-90 scleroscope as controlled by the carbon and alloy content. Their composition is essentially that of the carbon roll to which are added one or more special alloys. The maximum percentage of individual alloys used are: molybdenum 1.25, chromium 1.00, nickel 5.5, tungsten 1.5, vanadium 0.25. There are many varying combinations to effect the

properties desired. This type of roll is mostly used in rolling flat work, both hot and cold, particularly in the harder grades. Often the softer, machinable grades are used for small shapes and rod mill work.

(b) *Indefinite chilled iron rolls* are the American "grain" rolls (scleroscope hardness 40-90). They have an outer chilled face on the body but have no definitely formed chilled structure. Finely divided graphite is present at the surface which gradually increases in size with a corresponding decrease in hardness as the distance from the surface increases. This diminution of properties is gradual and these rolls present good wear and finishing qualities to considerable depths. The harder grades are used for hot and cold flat finishing work and the milder grades for deep sections, even with small rolls. The basis of the manufacture of indefinite chilled rolls is low phosphorus pig iron, together with at least 0.75% chromium and up to 2.50%. Other alloys such as nickel and molybdenum are usually added, singly or in combination, to develop specific properties of hardness and toughness such as are shown in the above definite chilled rolls.

(c) *Sand Iron Rolls* (scleroscope hardness 35-45) are those cast in sand molds in contrast to (a) and (b), which have the body cast in chilled molds. The metal in the grooves of the body is refined or densified by the use of cast iron rings set in the sand mold. Sand iron rolls are mostly used for intermediate and finishing stands on shape work but they are comparatively soft and their use is only justified in standard practice when there is insufficient tonnage available to warrant the use of the better and more expensive rolls which are available in the trade.

Manufacture—In the manufacture of definite chilled iron rolls, warm blast charcoal pig iron and worn out chilled iron rolls are used. Low phosphorus pig iron and worn out "grain" rolls are the basis of the indefinite chilled rolls. Both types are usually melted in a reverberatory or air furnace, similar to that used for the melting of iron for malleable castings (see "Malleable Iron," page 641).

When the furnace charge has melted and the bath formed made sufficiently hot a preliminary test is taken and cast in a sand mold, one side of which is a cast iron block to act as a chiller. The test is cooled, broken, and the fracture observed for the depth of chill. The chill on this test corresponds proportionally to that which will be found on the roll itself. A chemical analysis is usually made to check the physical readings and often a second test block is made to also check the first readings and stability of the bath. Should the readings show the depth to be either slightly shallower or deeper than that required, it may be increased by the use of sulphur, chromium, or low silicon white pig iron, or decreased with an addition of ferrosilicon, ferromanganese or high silicon graphitic pig iron. When the depth of chill and the temperature is judged to be correct the furnace is tapped into a lip ladle, which is then skimmed to clear the surface of accumulated dirt and slag. The metal is further held in the ladle until it has cooled to the proper temperature before casting. The mold for the roll casting is erected in a perpendicular position. The design of the mold is such that when the metal is poured a rapid centrifugal motion or "swirl" is produced as the metal rises in the mold, thus keeping the surface of the body clean. The heavy cast iron cylinder which comprises the body of the mold conducts heat rapidly from the molten metal, causing the formation of a hard white, or chilled iron surface layer on the body of the roll. The depth of this chill is controlled by the composition of the iron and it is varied to suit the requirements of the roll. The roll casting is allowed to remain in the mold for a period of 12 hr. to 6 days, depending upon its size. Some special alloy castings are taken out of the mold while still quite hot and transferred to an annealing furnace in order to control the cooling rate, or to be reheated to produce certain physical properties.

Application—Cast iron rolls have a wide range of application as they have a superior wearing and finishing quality over other types of rolls of equivalent hardness. They are almost universally used for hot rolling of flat work, such as two-high mills for sheet and tin rolling.

Opinions vary with reference to the application of cast iron, as well as alloy types of rolls, to various mills, due to the differences in mill practices and the varying qualities of finish required. The harder alloy cast steel rolls have an equivalent hardness to the softer cast iron rolls and their superior strength often demands their use. The harder, richly alloyed, definite chilled rolls approach in hardnesses to forged and hardened steel rolls and are competitive with them in the cold finishing of flat work.

Grade	Hardness, Scleroscope	Application
Definite chill (carbon or molybdenum chill)	55-72	Sheet and tin mill hot and cold rolls, 2- and 3-high plate mill rolls, jobbing mill rolls, wet and dry work rolls, 4-high hot strip mills, intermediate and finishing stands, rod, merchant, sheet, bar, skelp mills.
Definite chill (alloy iron)	50-90	Hot and cold nonferrous sheet and strip, 2- and 3-high plate mill rolls, universal mill rolls, work rolls, 4-high hot strip mills, cold rolls, finishing nonferrous and steel sheet.
Indefinite chill (grain alloy)	45-70	<i>Mild Hard</i> Light duty roughing for small merchant, bar mills. <i>Medium Hard</i> Intermediate rolls for merchant and bar and large structural mills. <i>Hard Grade</i> Finishing rolls for merchant, bar and structural mills, also for flat finishing on sheet bar and skelp mills; sizing, high mill, reeler and welding rolls for tube mills.
Indefinite chill (nickel alloy)	65-90	Finishing stands, sheet bar, skelp, strip and merchant mills. Work rolls, 4-high hot strip mills. Finishing nonferrous sheet and strip.
No chill (sand iron)	35-45	Mild duty small mill roughing to large structural finishing.

Cast Steel Rolls—The differentiation between cast iron and cast steel rolls cannot be made strictly on the basis of carbon content. In American practice the division between the two classes is made on the basis that iron rolls are of such compositions as will show apparent free graphite in the unchilled portions and steel rolls do not show graphite.

Composition—A small number of rolls are made from carbon steel, particularly for blooming and billet mills. The carbon range is usually 0.40-0.80% for roughing, and 0.85-1.25% for finishing rolls.

Alloy steel rolls have almost entirely superseded the carbon rolls. The majority of this type will be found within the following percentage range of analyses: Carbon 0.40-2.60, sulphur up to 0.12 usually 0.06% max., phos. up to 0.12 usually 0.06% max., manganese up to 1.25, chromium up to 1.50, nickel up to 1.50, and molybdenum up to 0.60. Lower carbon content gives greater strength while higher carbon affords increased hardness and wear resistance.

There are a small number of rolls made of higher alloy content than above indicated, but these are usually special purpose rolls.

In exceptionally large rolls where casting and heat treatment problems are intensified, or where hard surface and softer strong centers are desired, the roll may be made of an arbor for the center and necks, on which is shrunk a harder sleeve. These are known as "sleeve" rolls. Instead of scrapping solid back-up rolls which have become worn out or for any reason are not fit for mill use, they may be turned down and used for an arbor of a sleeved roll providing the metal is in good condition and sound.

Production—Steel rolls are generally cast from acid open hearth metal, although basic open hearth and electric furnace steel is sometimes used. The steel is cast in a dry sand mold in which suitable metal chills may be placed for more rapid solidification in certain portions of the roll. The mold is cast in a vertical position and the metal enters the bottom neck at an angle to the circumference so as to set up a swirling motion. This swirl carries any loosened sand or dirt to the center of the roll and results in a clean surface. A fairly large head and cope neck is necessary to feed the casting and avoid shrink holes. The cope neck is generally less strong than the drag neck, due both to the greater segregation at the upper portions of the casting and to the removal of more of the condensed surface metal in the enlarged area to reach finished size. After casting, the gates and head are removed from the rolls; it is then annealed or otherwise heat treated, and turned or ground to finished size.

Heat Treatment—Depending upon the service required, the hardness, and the composition, cast steel rolls are generally given one of the following heat treatments:

Single Annealing—Heat above the critical point for grain refinement and

Double Annealing—Heat well above the critical point for homogenizing and grain refinement, followed by heating only slightly above the critical point for further grain refinement.

Normalizing—Cool in air after double annealing to increase strength in special cases.

Rolls are graded by carbon range and general application as follows:

Carbon Range, %	Application
0.50-0.65	Where strength is the prime and only requirement.
0.70-0.85	Blooming mills, jobbing mill, plate mill and sheet mill roughers; muck mills.
0.90-1.05	Blooming mills, continuous bar mill roughers, backing-up rolls.
1.10-1.25	Blooming mills where breakage is not great; piercing mills; billet, bar, rail and structural mill roughers.
1.35-1.55	Rail mill intermediate stands; structural, continuous billet and continuous bar mills.
1.60-1.80	Continuous bar and billet mill intermediate stands; 3-high mill middle rolls.
1.85-2.05	Rail and structural middle rolls; and finishing mills where housing design is too limited for iron rolls.
2.10-2.80	Finishing rolls to meet unusual conditions.

The above applications are not a rigid classification due to the wide variation of conditions from mill to mill. Adjustments in carbon and alloy content are generally made to suit individual conditions.

Materials and the Manufacture of Bolts, Screws, and Nuts*

Bolts and Bolt Steels—The bolts that are most frequently used together with the steels from which they are made are listed in Table I.

Table I
Bolts, Screws, Nuts and the Steels From Which They Are Made

¹Set screws made from plain carbon steels are usually case hardened.

²C 0.14-0.20; Mn 0.60-0.90; P 0.045 max; S 0.05 max; Si 0.075-0.15.

³C 0.08-0.15; Mn 0.30-0.90; P 0.045 max; S 0.15 max.

⁴C 0.10-0.20; Mn 0.60-0.90; P 0.045 max; S 0.15 max.

⁵C in special 5 point range; Mn 0.70-0.90; P 0.04 max; S 0.04 max; Si 0.20-0.30; Mo 0.15-0.25.

The underlined steels are furnished by the manufacturer unless otherwise specified. Where two or more steels are underlined for the same product, the selection of the steel is optional. Where no steel has been underlined there is no accepted practice.

Steels Used in the Bolt Industry (S.A.E. Steels)

Steel 1010—Steel 1010 is used for some commercial bolts made by the cold heading process where strength is not the governing factor.

The minimum tensile strength is 50,000 psi.† The tensile strength of bolts made from this steel varies with the size of the material, the process of manufacture, and the heat treatment. This steel is commonly used where case hardened bolts are required.

Steel 1112—Steel 1112 is used for the same purposes and reasons as 1010, but the bolts made from this steel are made by the screw machine process. Products milled from cold drawn bars of this steel will have an approximate yield point of 70,000 and an ultimate of 80,000 psi. When normalized, the approximate tensile strength is 60,000 psi. When cold drawn, the yield point of this steel is relatively close to its tensile strength.

Open hearth steel of practically this analysis is used for nuts made by the cold punch process (Table I).

Steel 1020—This steel is generally used for cold headed bolts where a higher tensile strength is required than that of bolts made from steel 1010. Tensile strengths will be found to vary greatly between bolts of the upper and lower carbon limits of the analysis.

*This article was prepared by the Subcommittee on Bolts, Screws, and Nuts. The membership of the subcommittee was as follows: H. B. Pulsifer, chairman; C. L. Harvey, and C. E. Zwahl.

†The physical properties quoted in this practice are all based on machined tensile specimens.

The usual tensile strength of the heat treated bolt is 80,000 and the yield point 60,000 psi.

This steel is frequently used cold drawn for the manufacture of screw machine products. When cold drawn, it has a tensile strength of approximately 75,000 and a yield point of 60,000 psi.

A steel of practically this analysis, but with high sulphur, is used for the production of nuts made by the hot and cold punched processes (Table I). Where an open hearth steel is preferred to a Bessemer product, this steel replaces 1112.

Steel 1035—This steel is used for cold headed bolts where a higher tensile strength is required.

Bolts made from this steel are used for severe service conditions. After suitable heat treatment, the minimum tensile strength is 100,000 psi., combined with good ductility (minimum of 12% elongation in 2 in. and 45% reduction of area). The Brinell hardness range of 196-269 is found to be satisfactory for most classes of work. This is the lowest carbon steel satisfactorily double heat treated to close limits.

This steel is also used for screw machine products.

Steels 2330 and 3135—Products made from these steels are used to resist fatigue and shock and where a minimum of 125,000 lb. tensile strength after heat treatment is required.

After suitable heat treatment, the average physical properties obtained with these steels are as follows:

Yield point 110,000 psi.; tensile strength 140,000 psi.; elongation 16% in 2 in.; reduction of area 55%.

Brinell hardness ranges of 228-269, 241-286, and 269-321 are usually specified, depending upon requirements.

Special Materials—For special purposes, bolts are made from stainless, noncorrosive, and nonferrous metals.

Manufacturing Processes

Cold Heading—Cold heading is a process of upsetting by which the steel is made to flow into various shapes while it is cold.

The solid die type and the open die type are the two cold heading machines in which upsetting is accomplished. As a rule, the solid die type is used where the product is of short length and also with medium length products which require a high grade finish with close tolerance limits. The open die type is usually employed for long lengths of work which cannot be handled successfully in the solid die machine. Both types of machines are designed to operate with one or more heading strokes. The number of strokes required depends upon the shape of head and the amount of metal to be upset. Most types of machines are adapted for feeding wire up to $\frac{3}{4}$ in. diameter from the coils.

Cold upsetting is limited by the design of head, because only a certain amount of metal will flow into certain shapes. Shapes with corners and squares are hard to fill out.

All the steels listed in this article, except 1112, 1120, X1314, and X1315 are satisfactorily used for cold heading bolts.

Hot Heading—The operation of hot heading is similar to cold heading except that the steel is upset while it is hot.

Trimming—When the round or button shaped head has been upset in the cold heading operation, but some other shaped head, such as hexagon or square, is desired, it is secured by a trimming operation. This trimming operation consists of forcing the upset button head through a die of the required shape.

Burnishing—In order to obtain a smoother finish on the side of a head, the trimming operation is sometimes followed by a burnishing operation. This consists of forcing the head of the bolt through a die of the same shape as the trimming die, but of slightly smaller size.

Shaving and Pointing—If the top and bottom of the heads have not been properly shaped in the heading operation, they can be finished in a shaving operation which consists of cutting the top and bottom of the heads to desired form. This is particularly true of cap screw blanks.

Pointing or chamfering the end of the body of bolts or screws is accomplished by holding the blank in a suitable fixture and machining the end to the desired form. This operation prepares the blank for threading and gives the proper finish to the threaded end of the bolt as well as facilitating easy entrance into a tapped hole.

Threading—Cutting threads is accomplished by holding the bolt in a suitable fixture and presenting it to a die head which contains chasers. The chasers cut the threads on the bolt. When the desired length of thread is cut, the die head opens and releases the bolt.

Roll threading is accomplished by rotating the blank between flat or circular dies, upon the faces of which angular grooves have been cut which correspond to the proper form and lead of the thread to be rolled. These dies form the thread by displacing stock from below the pitch diameter of the thread and filling out the crest of the thread with the displaced metal.

Heat Treatment—For the heat treatment of screws, bolts and nuts made from carbon steels consult the article or the Composition and Heat Treatment of Carbon Steels in this Handbook.

Products made from 2330 steel are quenched in oil from 1475-1525°F., and products made from 3135 steel are quenched in oil from 1500-1550°F. and tempered according to the requirements of the finished bolts.

Composition, Heat Treatment, and Care of Sling and Crane Chain*

Scope—This article is intended to cover the heat treatment and care of open link mild steel chain (having a carbon content of not over 0.15%) and wrought iron crane or dredge chain. It does not cover stud link anchor chain, or chains over 2 in. in size which must in general be given special consideration. The portion of the article referring to periodic heat treatment refers only to mild steel and wrought iron chain, and not to cast steel, high carbon or alloy heat treated chain or low carbon steel or low carbon chain which has been carburized or cyanide hardened. It does not cover corrosion resistant steel or acid resisting bronze or Monel metal chain.

Introduction—The reliability of chain depends upon the quality of the welded links and the metal from which they are made. It is of paramount importance to ascertain if the chain is of ample size to sustain the safe working load. The quality of the metal should be carefully and thoroughly tested by the chain manufacturer, both for chemical and physical properties; a metallographic examination is also considered desirable.

Wrought iron for dredge chain usually has the following approximate chemical composition: Carbon under 0.05%; and manganese 0.06% max.

The average physical properties of wrought iron for chain are as follows: Tensile strength 46,000 psi.; yield point 23,000 psi.; elongation in 8 in. 26%; and reduction of area 40%.

Other tests that are often performed on wrought iron for chain are: Cold bend, quench bend, and drift tests. In addition, a cold feathering test may be applied by flaring the end of the bar under a hammer. This test is an aid in judging the workmanship put into the welded fagot. The results of these tests should show a high degree of ductility, and a fibrous, silky fracture free from bright spots.

Because mild steel requires different welding temperatures and methods than wrought iron, a satisfactory weld may not be obtained if the two materials are mixed in rerolling or reheating processes. To determine if an admixture of wrought iron and steel has been used, metallographic examination should be resorted to.

Low carbon steels are largely used for small chain other than sling chain, but in large sizes there are welding difficulties which are not encountered with wrought iron. Most chain above 1½ in., therefore, is made of wrought iron.

Normalizing, Testing, and Inspecting After Welding

Normalizing—After the welding operation has been properly performed, the welded or adjacent portion will not need a normalizing treatment to refine the structure, but in the case of large chain, such as ship anchor chains, portions of the link adjacent to the welds have been heated to or near the welding temperature, and if not hot worked, a weak, coarse, crystalline structure is developed which requires a normalizing treatment for refinement.

To normalize, the chain is placed in the annealing furnace, usually of the car bottom type, and heated until the complete charge, top, center, and bottom is at a temperature of 1750°F. The charge is held at this temperature for 10-15 min., or until the heat has completely penetrated the work. The car, if the car bottom type has been used, is then drawn out and the chain allowed to cool in the air. In other furnace types, the furnace doors may be opened or the chain removed from the furnace and allowed to cool on the shop floor.

Proof Test and Inspection—After cooling, the chain is proof tested. The test consists of fastening one end of the chain to the head of the testing machine and the other end to the anchor crosshead. The proof load for proof coil (steel) chain is usually 50% of the breaking load. For high grade wrought iron crane chain

*This article was prepared by the Subcommittee on the Heat Treatment and Care of Sling and Crane Chain. The membership of the subcommittee was as follows: A. V. deForest, Chairman; F. E. McKinney, C. G. Lutts and L. W. Hopkins. (Revised in 1938 by C. G. Lutts and L. W. Hopkins.)

the proof load is usually established at 33-38% of the breaking load. The justification for lower proof for wrought iron chain lies in the fact that it is often used in places where it is called upon to absorb high impact loads. It therefore should not be elongated in the proof test beyond that point necessary to detect defective welds or materials. Each link is then carefully inspected for flaws or other defects. Link measurements are made to determine if the chain has stretched beyond the specified dimensions. All chain suffers permanent elongation after the proof test.

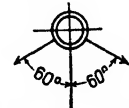

After subjecting the chain to a proof test, it may be annealed and the yield point thereby lowered. This step makes overloading more evident and to that extent increases the factor of safety. Because of the increased cost this operation is usually dispensed with, so the problem should be referred to the manufacturer before this particular annealing operation is specified.

Care and Use of Chain—Overloading is probably the most serious service abuse to which chain is subjected. A new chain may be impaired by overloading the first few times it is used. The elasticity of the chain metal is sufficient to take care of the safe working load. If the chain has not been overloaded, or stressed beyond the yield point, the chain will regain normal shape as soon as it is relieved of its load. When stressed beyond the yield point by an overload the metal does not go back to its normal condition or shape after the load is removed. When the yield point of the metal is once passed by an overload, the chain is never as strong under impact as before it had been stretched. If the chain is carefully measured at frequent intervals, any elongation that is not the result of wear is sure proof of overload.

Improper application of the chain sets up stresses that are far in excess of those caused by the weight of the load lifted, and which may be the cause of sudden failure. These increased stresses may be caused by any of the following:

1. Sudden application of the load, shocks, and sudden jolts.
2. Twisting of chain, kinks in chain, and crossing of chain.
3. Bending of links around sharp corners.
4. Excessive angles beyond that for which the sling is designed between the branches or legs of a double sling chain.

Table I
Safe Load in Pounds for Sling Chains Under Different Loading Conditions

Nominal Dia. of Chain Stock in in.	   			
	Single Leg Sling Capacity in lb.	Double Leg Sling Capacity in lb.	Double Leg Sling Capacity in lb.	Double Leg Sling Capacity in lb.
1/4	1,060	1,060	1,480	1,850
5/16	1,655	1,655	2,320	2,900
3/8	2,385	2,385	3,340	4,170
7/16	3,250	3,250	4,550	5,680
1/2	4,240	4,240	5,940	7,420
5/8	5,370	5,370	7,520	9,400
3/4	6,630	6,630	9,270	11,600
7/8	9,540	9,540	13,300	16,700
1	12,960	12,960	18,100	22,700
1 1/8	16,950	16,950	23,750	29,600
1 1/4	20,040	20,040	27,000	35,020
1 1/2	24,750	24,750	34,600	43,300
1 3/4	29,910	29,910	41,800	52,300
1 7/8	35,600	35,600	49,800	62,250
2	41,800	41,800	58,500	73,200
2 1/4	48,450	48,450	67,800	84,800
2 1/2	55,300	55,300	77,800	96,800
2 3/4	63,300	63,300	88,600	111,000

Failure Caused by Repeated Loading—Chain may break without showing elongation if loaded below the yield point a sufficient number of times. Failure may take place by ordinary fatigue, but is much more likely to occur by the following mechanism: Through the repeated peening action of the chain links against each other and their being dropped and hit against stone or metal, the surface of the soft iron is given a work hardened skin. Under impact loads, usually difficult to

avoid, this skin is broken and the crack constitutes a notch which localizes stress and weakens the chain under conditions of further impact or repeated load. This hard skin may be removed and the impact strength of the chain maintained by periodic annealing. How often this is desirable depends on the particular service involved.

Angle of Sling Chains—The angle between the legs of the branches of a double sling chain should always be taken into consideration, especially when handling

Table II
Reduced Diameter of Link Stock in Chain Slings
Original Safety Factor = 7

Chain Size, in.	Reduced Safety Factors—

Links to be measured at point of greatest wear.

Example:

A ½ in. chain is worn to about 0.40 in. in dia.
The remaining safety factor, full load, is (from table)
about 4.5.

heavy loads. As this angle increases, the angle between the legs and the work decreases. This reduces greatly the safe working load of the chain, because as the angle between the two legs of the chain increases the tension in each leg is also increased. The safe load in pounds for double sling chains, using different angles between the legs, is given in Table I.

Factor of Safety—Chain is always manufactured with a factor of safety sufficient to take care of a reasonable amount of abuse, but even this is of little avail with the careless handling which is given some chain.

The cold working caused from overloading will increase the breaking load, but decreases the ductility and resistance to shock, thereby reducing the factor of

safety. Chain links are reduced in diameter, due to dirt, grit, and abrasives grinding between the links when the load is applied. As the diameter is reduced, the factor of safety is lowered. In Table II is given the factor of safety for reduced chain links caused by wear.

If properly carried out, annealing will automatically increase the factor of safety, except where the link is reduced in diameter by wear. Annealing should not be done periodically as a "cure all," but carried out in conjunction with careful inspection. Inspection and measurements of the chain will give notice of any abuse. Wear, however, will cause elongation of the chain, so it is necessary to distinguish between this effect and the elongation caused from overload.

Annealing can restore ductility only in the metal of the reduced cross section and does not restore the chain to its original condition because the effects of the permanent deformation to the links are unchanged. No chain should be used on heavy work after it has been badly overloaded and has thereby become deformed. The tensile strength may not be impaired but the deformation of the original links considerably reduces the reserve of shock resistance in the links.

Chains that run over sheaves, such as hoist chains, should not be heat treated, except by the manufacturer, because these chains are very carefully proof loaded and gaged to sheave dimensions before being put into service.

COMPOSITION AND HEAT TREATMENT OF SLING AND CRANE CHAIN

General—This article covers the process to be followed for the annealing of sling and crane chain.

Process—The process of annealing chain consists of loading the furnace, heating, and cooling the chain.

Loading the Furnace—Place the chain in uniform layers on the furnace bottom so as to expose maximum surface area. To prevent scale from forming, a hood should be placed over the chain and the edges of the hood sealed with sand. The openings of the hood are sealed with fire clay.

Table III
Annealing Treatment for Iron and Steel Sling and Crane Chains

Dia. of Chain Link, In.	Iron Chain Annealing Temp., °F. ¹	Steel Chain Annealing Temp., °F. ¹	Time of Holding at Temp., hr.	Cool in
¼ to ½	1350-1375	1600-1650	¼	Air
¾ to 1½	1350-1375	1600-1650	¾	Air
1½ and above	1350-1375	1600-1650	2	Air

¹In case of doubt as to whether the chain to be treated is iron or steel, a temperature of 1350-1375°F. should be used. This practice will thoroughly relieve any strain or work hardening from iron chain without excessive scaling or softening of chain. This low temperature will theoretically produce some grain growth or recrystallization in steel chain, but it has been determined by experience that this has a negligible effect on the chain and is to be preferred to excessive scaling.

Heating—Heat to the temperatures given in Table III and hold at temperature for the time specified. The heat should thoroughly penetrate the work, and the top, center, and bottom of the charge should reach approximately the same temperature.

A sufficient number of thermocouples should be used to assure uniform temperature throughout the charge. A pyrometric record of the heating operation should be delivered with the annealed chain.

Cooling—After the chain has been held at the annealing temperature for sufficient time, the charge is pulled onto the cooling platform, or onto the floor. The chain should be spread in single layers, with ample space between each chain, so as to cool rapidly and uniformly to room temperature.

After annealing it is desirable that the chain be proof tested and reinspected for weld defects and defective links. The annealing treatment serves the purpose of burning off dirt and grease adhering to the chain, and thus facilitates inspection.

Precautions to Be Used with Chain

- Don't overload a chain.
- Don't apply a load to a chain suddenly.
- Don't fasten chain over sharp corners or edges.
- Don't cross a chain, twist it or put a kink in it.
- Don't take chances; if a chain does not look safe, or does not pass inspection, scrap it.
- Don't use a chain at small angles to the work.
- Don't force a chain or hook into a place by hammering.
- Don't carry a load on the point of the hook.
- Don't insert the point of the hook into a link.
- Don't let the load rest on the chain.
- Don't drag a chain from under the load.
- Don't roll over jobs with chain, use ropes.
- Don't think a chain is good because it is new; a new chain can be ruined by a single overload.
- Don't trust a chain with stretched or stiff links.
- Don't allow heavy weights to fall on chain.
- Don't allow chain to be exposed to extremely cold weather for any length of time.
- Don't apply sudden loads to extremely cold chain.
- Don't carry an unbalanced load.
- Don't, under any circumstances, use chains that are excessively pitted or corroded.
- Don't forget constant and careful inspection.

Wire Rope or Cable*

Introduction—Wire Rope is one of the most reliable structural materials available. It has the decided safety feature of indicating by surface inspection when it should be replaced. The wear and broken wires disclosed by such inspection, where corrosion is not present, will reasonably indicate the remaining strength. Slings made from wire rope, employing proper fittings, furnish the safest method for handling material.¹

There are six qualities of wire rope in commercial use as follows:

Grades	Approximate Carbon Content
Iron	0.05-0.15%
Traction steel.....	0.20-0.50%
Cast steel	0.30-0.60%
Extra strong cast or mild plow steel.....	0.55-0.70%
Plow steel	0.65-0.80%
Improved plow steel.....	0.70-0.85%

There are four standard constructions of wire rope; namely, 6x7, 6x19, 6x37, and 8x19. The figures mean that the rope is composed of 6 strands of 7 wires each, 6 strands of 19 wires, et cetera. There are, however, many variations in strand construction and the number of wires per strand may vary from 7-61 or even more should conditions require them.

To attain the different physical properties required in the various constructions, the individual wires of which a wire rope is composed are specially heat treated and cold drawn after the heat treatment, which produces the necessary toughness and strength. Any attempt, therefore, to eliminate the effect of service overstraining by annealing or any form of heat treatment, such as is given to chain, would obviously destroy the original properties of the wire obtained by the cold drawing. Such a heat treatment would ruin wire rope.

Qualities of Wire Rope

Iron Rope—Iron Rope is low in strength and soft as compared to steel rope, so consequently will stand little abrasion. It is pliable and tough, but its field is limited to uses where the abrasion is slight and the drums and sheaves are large. It is usually recommended for use on drum types of passenger elevators, for compensation and governor ropes, or for transmission of power by wire rope. It is not adapted to general hoisting or guy ropes. It is generally only furnished in the 6x7 and 6x19 standard construction.

Traction Steel Rope—This rope was developed particularly to meet the requirements of traction elevators on which it was necessary to have a high fatigue resistance, coupled with pliability and a softness so that the rope would not cut the sheaves. Traction steel rope therefore is not as strong as the Cast Steel Grade of rope.

Cast Steel Wire Rope—Although twice the strength of iron rope, cast steel wire rope is, comparatively speaking, a low strength steel hoisting rope and is only suitable for what is termed moderate duty. It is used on freight elevators where the operating tension is relatively low, as track cables on short span cableways, as hoist ropes on slow speed shallow mine installations that are equipped with large drums and sheaves, or as haulage rope under very favorable operating conditions. If the duty be heavy, the stronger and tougher grades of steel should be used.

Extra Strong Cast or Mild Plow Steel Rope—This rope is a stronger grade of cast steel and is substituted for cast steel rope where a slight increase in the factor of safety is desirable. In practically all cases the higher strength ropes prove more economical for general service.

Plow Steel Rope—Plow steel rope is made of high strength wire considerably stronger than either the cast steel or extra strong cast steel grades. This rope is well suited for the average hoisting conditions where loads are not excessive, where

*Prepared by Dr. H. C. Boynton and A. J. Morgan, John A. Roebling's Sons Co., Trenton, N. J., for the Subcommittee on Wire Rope and Cable. The membership of the subcommittee was as follows: B. B. Bachman, Chairman; H. C. Myra, H. Styri, and Dr. H. C. Boynton.

¹The terms "Cable" and "Wire Rope" are generally considered to be synonymous. However, when the term "Cable" is substituted for "Wire Rope", it is usually preceded by a descriptive adjective which places it in a more or less definite class; such as, a "Track Cable" on a cableway, or "Bridge Cable" as used in suspension bridges.

the sheaves are of normal diameter, and where the abrasion is not too severe. Plow Steel Rope has a general use such as on derricks, mine and coal hoists, cableways, cranes, conveyors and logging ropes.

Improved Plow Steel—This grade of rope is generally given a trade name by the manufacturers. It is a high strength rope recommended in place of the plow steel grade where the abrasion is severe or the rope is subjected to severe shocks, vibrations, or fatigue stresses. This rope is particularly adapted for severe mine duty, for logging lines, scraper dredge and rigging ropes, heavy cranes, ballast unloader ropes and excavating machinery.

Constructions of Wire Rope

Standard Coarse Laid Rope—The 6x7 wire rope construction is called "Standard Coarse Laid Rope". It is made of 6 strands of 7 wires each closed around a hemp center. It is much stiffer than standard hoisting rope and requires larger sheaves. This rope is used for heavy haulages with large equipment, wire rope transmissions, tramways, well drillings and sand lines.

Table I

1/4	3/4	0.10	2.1	2.3	2.5	2.9

Standard 6x19 Construction or Standard Hoisting Rope*—This rope is made of 6 strands, each of which is formed by twisting 19 wires together. The strands are finally closed around a hemp center. It is generally accepted that rope made with strands having not less than 16 and not more than 25 wires each belong to this general 6x19 class. This rope construction is more generally used for hoisting and other rope uses than all other constructions and is usually considered to be a flexible rope.

Table I gives the important sizes and properties for a Standard Hoisting rope of 6x19 construction made from Improved Plow Steel. The two constructions most generally furnished under the 6x19 Improved Plow Steel are the 6x19 Seale construction and the 6x19 Modified Seale or Filler wire construction, as illustrated in Figs. 1a and 1b.

6x37 Rope Construction—This rope consists of 6 strands, each of 37 wires. When each strand of the rope has not less than 29 or more than 46 wires composing it, the construction is generally considered in this class. This rope construction is generally termed as "Extra Flexible Hoisting Rope" and is usually recommended in place of "Standard Hoisting Rope" when the sheaves are found to be too small for the latter. The wires in this rope are necessarily much finer than those used in the standard hoisting rope with 19 wires to the strand and consequently are not as suitable to withstand severe abrasion.

*The 6x19 construction is probably used more often than the others, so much so that it is called "Standard".

8x19 Rope Construction—This construction is composed of 8 strands of 19 wires each closed around a hemp center. It is generally used where sheaves of small diameter must be employed and the abrasion is light. This rope construction is generally considered to be an "Extra Flexible Hoisting Rope" and sometimes may be considered to be interchangeable with 6x37 rope construction. The metallic area of the 8 strand rope is not so great as the 6 strand rope, but under severe bending conditions the decrease in strength is largely offset by the greater pliability.

Fig. 1a—Seale construction (6x19)

Fig. 1b—Modified Seale construction (6x19)

This rope distorts from its circular cross section more readily than a 6 strand rope so conditions of service which cause crushing require a 6 strand in preference to an 8 strand rope.

Proper Working Loads

—It is never advisable for the working load of wire

rope, particularly running ropes, to exceed one-fifth of the breaking strength. This means that the factor of safety should be not less than five. To determine proper working load, divide the breaking strength by the proper factor of safety. For example, a 1 in. diameter 6x19 Improved Plow Steel Rope has a breaking strength of 42 tons (Table I), and with a factor of safety of five, the proper working load would not be over 8.4 tons.

Factors of safety in excess of five, varying up to eight and even more, are often required for safe and economical operation. The proper factor of safety for a wire rope should be determined by careful and thorough consideration of all pertinent data. Such data should include all loads; acceleration; deceleration; rope speed; rope attachments; the number, size and arrangement of all sheaves and drums; existing conditions causing corrosion and abrasion; length of rope in service; economical rope life and the degree of danger to life and property.

Proper Sizes of Sheaves and Drums—To obtain most economical wire rope service, sheaves and drums should be carefully examined for proper size, free running, and proper groove diameters. It is advisable to design the sheave and drum equipment so that the tread diameters are approximately as follows:

Recommended Average Diameters for Sheaves and Drums

- For 6 x 7 Rope, 72 times rope diameter
- For 6 x 19 Rope, 45 times rope diameter
- For 6 x 37 Rope, 27 times rope diameter
- For 8 x 19 Rope, 31 times rope diameter

For economical service, various conditions allow, and often require, changes from these diameters. For example, on larger hoisting installations, sheaves for use with a 6x7 rope are sometimes set at 96 times the rope diameter and, for a 6x19 rope, sometimes as high as 90 times the rope diameter.

It is also true that for certain classes of service, ratios smaller than these are possible and economical, although larger diameters give increased life, but it is advisable never to allow the sheave and drum diameters to be set below the following:

Minimum Diameters for Sheaves and Drums

- For 6 x 7 Rope, 42 times rope diameter
- For 6 x 19 Rope, 30 times rope diameter
- For 6 x 37 Rope, 18 times rope diameter
- For 8 x 19 Rope, 21 times rope diameter

Rope and cable subjected to intense sheave or drum pressures or operating under conditions of severe heat are often manufactured with metallic centers instead of the usual hemp core. This center may be in the form of a strand or an independent wire rope. If such a center be used, the rope strength given in Table I may be increased by 7½% and the rope weight by 10%.

Storage—Particular care should be taken in storing wire rope to avoid damage. The rope should be stored in a dry place. It should not be allowed to become so hot as to injure the hemp center. To prevent destructive corrosive action on the steel, the storage place should be free from chemicals or gas from same.

Handling—Care should be taken in handling so that the rope is neither twisted nor untwisted. Kinks of any nature or the pulling down of loops to small diameters should be avoided. The wires are damaged beyond the elastic limit at such points and in subsequent service will break rapidly, producing a condition which is erroneously termed a bad spot in the wire rope. A spot like this is due to a kink placed in the rope either prior to or during its service.

Cutting—Before the actual cutting operation, proper servings* should always be placed on each side of the point where the rope is to be cut. Such a procedure is absolutely necessary in order to prevent the unlaying or the rotating of the strands. It is advisable to use a minimum of three servings on each side of the cut. The proper method for applying servings is shown in Fig. 2.

Fig. 2—Applying servings on a wire rope.

1. Wind the serving wire on the rope by hand, keeping the coils together and considerable tension on the wire. 2. Twist the ends of the wire together counterclockwise by hand so that the twisted portion of the wires is near the middle of the serving. 3. Using "Carew" cutters, tighten the twist just enough to take up the slack. Do not try to tighten the serving by twisting. 4. Tighten the serving by prying the twist away from the axis of the rope with the cutters. 5. Tighten the twist again as in (3). Repeat (4) and (5) as often as is necessary to make the serving tight. Cut off the ends of the wires and pound the twist flat against the rope. 6. The appearance of the finished serving.

Attachments—There are several ways in which the rope ends may be secured. The desirable one, and the one which develops 100% of the rope strength, is a socket connection. The proper method of attaching sockets is shown in Fig. 3.

In preparing the wire for socketing, the hemp center is entirely removed and the "brush" of separated wires is never dipped over three-quarters of its length in the acid so no trouble from corrosion occurs, moreover a slight film of hydrochloric acid acts as a flux to assist the amalgamation of the zinc to the "brush".

A thimble spliced in one end of the rope is often used for an attachment. Its efficiency varies from 75-90% of the rope strength, depending upon the rope size.

*Servings are sometimes called "seizings," and are soft wire fastenings secured around the rope to maintain its manufactured condition.

The thimble connection is also used with wire rope clips. This attachment has about the same efficiency as the splice. It is essential, however, in order that maximum efficiency be obtained that the clips be applied one rope lay apart, tightened securely and the U-bolts of the clips always placed on the dead end of the rope. The use of improperly designed clips or improper clip attachments results in strengths as low as 60% of the ultimate strength or less. The thimble is also used with 3-bolt clamps and this efficiency, when the clamps are properly designed, runs about the same or in excess of that obtained by use of clips. Clips and clamps should be tightened after about an hour's run and at the regular inspection intervals after that. It is essential in all of these connections employing the thimble that a proper design of wire rope thimble be used. It should be one which has a sufficient size of eye and also one which furnishes the proper support to the rope.

Lubrication—The subject of wire rope lubrication is one which should be given careful consideration. Light applications of a comparatively thin oil are usually sufficient for elevator ropes which are not exposed to the elements; while the conditions to be met in a mine shaft require a much heavier lubricant and a protector against the severe inroads of corrosion.

It is not possible for the manufacturers to place sufficient lubrication within a rope to last throughout its entire life. It is essential that a wire rope be lubricated internally as well as externally to reduce internal friction and protection against corrosion. When corrosion starts inside a wire rope its injurious effect can seldom be seen and cannot be arrested before the service and the safety of the wire rope are affected. The lubricant used should preferably be one recommended by the rope manufacturer.

Fig. 3—Socketing wire rope.

1. Measure from end of rope a length equal to basket of socket. Serve at this point with not less than three wraps. Cut out hemp center—open strands. 2. Separate wires in strands, straighten by means of iron pipe, cleanse with kerosene oil, wipe dry. 3. Dip wires into one-half muriatic acid, one-half water (use no stronger solution). Keep wires in long enough to be thoroughly cleansed—wipe dry, serve end that socket may slip over all of wires. 4. After placing on socket, cut serving wire at top—have all wires evenly distributed and even with top of basket—place fire clay around bottom of socket. 5. Pour in molten pure zinc—do not use babbitt. 6. Remove all servings except one nearest socket. After cooling it is ready for service.

The correct lubricant should be one which when applied hot will penetrate thoroughly into the rope and on cooling congeal sufficiently so that it will not drip off, but rather form a plastic coating on the wire. The lubricant should

also be free from ingredients which would be injurious to the rope. Improper lubricants which harden on the surface will result in more damage than benefit, because they keep subsequent lubricants out and let in and keep in moisture. This condition accelerates corrosion.

In the American Engineering Standards Committee Paper, dated Feb. 24, 1927, is a set of rules for the selection of wire rope lubricants.

Sheave and Drum Grooves—Improper sheave or drum grooves undoubtedly result in more damage to wire rope than does any other single factor, so consequently cause irregular and uncertain rope service. It is essential that the grooves be of sufficient size for operating with new ropes when installed. The grooves are generally worn down by service; the degree of wear being dependent upon the radial pressure and the material of which the sheave is made. The grooves wear to the diameter of the worn rope operated over them and consequently become small for the new rope. This causes the new rope to receive extra abrasion and distortion which is very detrimental. Sheaves and drums should be inspected before the installation of the new rope and where the groove diameters have worn to limits in excess of those given below, the sheaves should be replaced or remachined so that the groove diameter will correspond to the following limits:

For ropes $\frac{1}{4}$ – $\frac{1}{2}$ in. dia., inclusive, groove dia. should be $\frac{1}{16}$ in. greater than rope dia.
 For ropes $\frac{3}{4}$ – $1\frac{1}{4}$ in. dia., inclusive, groove dia. should be $\frac{1}{8}$ in. greater than rope dia.
 For ropes $1\frac{1}{2}$ – $2\frac{1}{4}$ in. dia., inclusive, groove dia. should be $\frac{1}{4}$ in. greater than rope dia.
 For ropes $2\frac{1}{2}$ – $3\frac{1}{2}$ in. dia., inclusive, groove dia. should be $\frac{3}{8}$ in. greater than rope dia.

Removal of Ropes from Service—It is first necessary to determine the factor of safety to which a rope may safely deteriorate. The importance of this will be appreciated since ropes in some places would not endanger life or property should they break. Breakage in other places would be highly dangerous, so the minimum factor of safety must be set for such installations. In general, ropes which have the outside wires reduced 50% of their diameter by abrasion are likely to break rapidly. With some ropes many wires start breaking before this amount of abrasion is reached. It is, therefore, the number and the distribution of the broken wires together with the amount of abrasion which would indicate the remaining strength of the wire rope. The proper way to count a rope for broken wires is to count the number of such broken wires by strands per rope lay. By rope lay is meant that length of rope in which a strand makes one complete revolution about the rope axis. The worst rope lay counted should be the one on which to base the estimate of remaining strength or on which to base the decision as to whether or not the rope should be removed from service. The rapidity with which broken wires develop indicates the degree of fatigue and where the broken wires develop rapidly the rope should be carefully watched, since it will, undoubtedly, have to be removed soon thereafter.

An estimate of remaining strength or decision as to the safety of the rope cannot safely be made where corrosion is a factor, due to acid mine waters and corroding gases. When corrosion occurs in a wire rope it is impossible to estimate remaining strength or state that the rope is safe without an actual ultimate strength test of the rope. Should this test prove satisfactory there is no definite assurance that the balance of the rope is equally as good as the piece tested.

Long life for wire rope depends upon:

- Proper quality of wire used;
- Right construction for installation at hand;
- Large sheaves, with proper grooves;
- Correct lubricants, applied hot for internal and external lubrication;
- Prevention of corrosion;
- Careful supervision to prevent "kinking" or "looping" in installation, and overloading in service;
- Keeping count of broken wires, looking out for fatigue.

Wire rope is one of the most reliable of structural materials, but it should be realized that a wire rope is essentially a machine, in that it is composed of many parts functioning as a unit with the individual wires acting as bearing surfaces, and as such is subjected to pressure and wear. It will be readily apparent that the ultimate service will depend primarily upon its maintenance and care.

Nonferrous Section

A Record of Appreciation

This section of Metals Handbook was prepared by the Institute of Metals Division of the American Institute of Mining and Metallurgical Engineers through a co-operative arrangement with the American Society for Metals.

The Nonferrous Data Sheet Committee of the Institute of Metals Division, in charge of the preparation of the nonferrous articles, has again included much new material of a practical nature on the properties, technology, and applications of nonferrous metals and their alloys.

The members of the Committee, the authors and subcommittee members have given their whole-hearted co-operation in accumulating and presenting the data for this section of Metals Handbook. We wish to take this opportunity of extending our appreciation to all of the individuals mentioned above and to the American Institute of Mining and Metallurgical Engineers for this splendid assistance and the outstanding results it has produced. Their work has provided for the nonferrous industry a reference volume of distinct importance and helpfulness.

The personnel of the Nonferrous Data Sheet Committee for the 1939 edition of Metals Handbook was as follows:

Jerome Strauss, Vanadium Corporation of America, Chairman
W. L. Fink, Aluminum Company of America
W. E. Remmers, Electro Metallurgical Corporation
E. E. Schumacher, Bell Telephone Laboratories
E. M. Wise, International Nickel Company
Lyall Zickrick, General Electric Company

MEMBERS OF NONFERROUS DATA SHEET COMMITTEE IN THE PRODUCTION OF PREVIOUS EDITIONS OF THE HANDBOOK

R. S. Archer, Republic Steel Corporation, Chairman, 1927-1933
T. S. Fuller, General Electric Company, 1927-1933
L. W. Kempf, Aluminum Company of America, 1933-1936
C. H. Mathewson, Yale University, 1927-1933
Arthur Phillips, Yale University, 1934-1936
A. J. Phillips, American Smelting and Refining Co., 1932-1934
N. B. Pilling, International Nickel Company, 1932-1936
W. G. Schneider, The American Brass Company, 1932-1936
F. L. Wolf, Ohio Brass Company, 1927-1933

Hot Plastic Working of Nonferrous Metals

By Dr. C. H. Mathewson*

Hot working is usually defined as working above the recrystallization temperature, so as to insure recrystallization and recovery or retention of normal properties in spite of the plastic deformation.

A satisfactory scientific foundation for the generality of hot working operations requires the development of complete information in the following directions: (a) Stress-strain curves at temperatures throughout the potential hot working range and with a rate of application of stress comparable to that desired in the intended hot working operation. (b) From such curves an evaluation of the energy requirements for economical operation and of the toughness or ability of the metal to withstand the process. Thus, the temperature selected for hot working should prevent any great increase in yield point of the metal during working, that is, should yield a flat stress-strain curve and there should be adequate elongation before fracture. (c) The effect of prior structural condition of the alloy and in particular of natural impurities. (d) The requirement of special properties in the metal imposed by the special mechanical characteristics of any given process, such as drawing, extrusion, forging, rolling, swaging. Thus, in drawing, the metal must have strength to support the plastic alteration through the die, while in swaging the metal is itself supported during deformation and may be worked at its minimum both of plasticity and strength.

The literature of metal technology shows no systematic or satisfactory accumulation of data on these points or development of other criteria for judging the hot working quality of metal. The performance of a metal in such operations is usually estimated in a rough, provisional manner by reference to its softening temperature after cold work, with an increment allowed for the higher temperature necessary to permit virtually instantaneous softening in a rapid deformational process. Data on ordinary static tensile strength and ductility at elevated temperatures are now available¹⁰ for many of the ordinary commercial alloys, and are of certain value in indicating proper working temperatures. The details of performance are then settled purely by the method of trial and error. Similarly, the effect of impurities and the requirements of special processes must be established by a suitable empirical testing procedure. There is a general tendency to credit a high value of reduction of area in the hot tension test, accompanied by moderate tensile strength, as especially indicative of useful plasticity. For example, in the tests reported by Price⁵ copper has a percentage reduction of area exceeding 90 in the temperature range 930 to 1830°F., with tensile strength falling gradually from about 9,000 to about 1,200 psi. In the table at the end of this article, 1550° is given as an optimum hot rolling temperature for copper to maintain softness, but the metal may be satisfactorily hot rolled at all temperatures indicated above, though with some difficulty at the highest temperatures on account of its extremely low strength in this region.

Certain established practices have arisen, perhaps with little attention from the scientific point of view, and rather definite statements may be made, as in the article on Hot and Cold Working of Copper Alloys in this Handbook concerning the adaptability of industrial alloys to the various hot working operations of extrusion, stamping, pressing, rolling, and piercing. Much information of this character may be found in the various articles on metal technology in this Handbook.

For rapid deformations as in stamping or forging the requirements of (a) may be realized in a drop hammer test in which the decrease in height of a cylindrical sample is plotted against the energy of the blow. Commonly, various approximations are accepted, such as compression for a given blow plotted against temperature, or composition,^{8, 9} from which suitable temperatures, or compositions, may be selected when attention is also directed to the manner in which the specimen stood the plastic alteration (absence of edge-cracking).

When the constitution of an alloy changes with temperature, impact tests on notched bars may show with particular clarity the existence of favorable and unfavorable temperature ranges of toughness. Thus the width of the brittle range in brass in the vicinity of 900°F. and its change with composition, as well as the effects of lead and tin are brought into prominence by the Izod test.^{11, 12}

However, there are good indications of this weakness in the ordinary tension test for elongation or reduction of area⁴ and the writer is not aware that any test

*Professor of Metallurgy, Yale University, New Haven, Conn.

revealing hot shortness, or far reaching plasticity and toughness, can be used as more than a general guide to direct experimentation with the particular equipment in which the given alloy must be deformed.

The empiricism necessary in this work is well stated by Morris:¹⁰

"For instance we wish to extrude a metal M. We know that we can extrude another metal Q at temperature T. We make a drop hammer test of metals M and Q and find that in order to obtain the same reduction in height as we find in metal Q at temperature T, we must heat metal M to temperature T'. T' is therefore the temperature at which we first try to extrude the metal M, with fair assurance that we shall be able at least to force the metal through the die. Much the same kind of reasoning can be applied to hot rolling. The tendency to crack in extrusion and rolling, however, must be ascertained largely through experience."

Concerning the effect of impurities, embrittlement due to segregation of a weak constituent in grain boundaries (that is, lead in alpha brass) and the great rise in resistance to deformation generally produced by solid solution even of small amounts of alloying elements (principally responsible for the contrast in properties between commercial and extremely pure metals) have been studied more in relation to cold

Fig. 1—Shear strengthening of single crystals of cadmium, according to Schmid and Boas.¹²

Fig. 2—Shear strengthening curves of metal crystals, according to Schmid and Boas.¹⁴

working than hot working but have brought certain well recognized limitations into commercial practice. For example, lead above a few thousandths of a per cent prevents the commercial hot working of alpha brass, but with Muntz metal, due probably to a more favorable distribution attending the structural adjustment of alpha and beta with temperature in the hot working range,⁹ lead in considerable quantity does not prevent the majority of hot working processes. Similarly, tin bronzes which contain the ($\alpha + \delta$) eutectoid show marked brittleness in the Izod test and cannot be successfully hot worked, while tin in solid solution yields good hot working bronzes.¹¹

Annealing or recrystallization temperatures as ordinarily determined do not properly define the softening points of metal while in a process of rapid deformation. The effect of temperature and rate of loading on hardening is particularly marked in this region of temperature as may be seen from Fig. 1. The solid curves show strengthening in single crystals of cadmium under a load applied at the rate of 140 psi. per minute and the dotted curves, strengthening under a load applied at a rate 100 times greater. It thus appears that in a region of low temperature where there is virtually no spontaneous recovery towards initial properties and in a region of high temperature where the recovery is substantially complete during the test, changing the temperature or the rate of loading has little effect on the strain hardening. In an intermediate region of temperature, which undoubtedly corresponds to the temperature at which ordinary softening and recrystallization begin in severely strain hardened polycrystalline material, much or little recovery may occur depending upon the rate of loading; and the final strain hardening of the metal varies according to these conditions. In the present case, the crystal after a shear of 400% at the

higher rate has a resistance to further shear of about 850 psi. and after the same amount of shear at the slower rate, a resistance of about $\frac{1}{2}$ this value.

Resolved stress, shearing deformation curves for room temperature loading have been obtained for the majority of common metals as shown in Fig. 2. As the slope of such curves is governed by the amount of recovery during the test, it appears that the tendency of the metals to recover from the strain hardening influence during deformation at ordinary temperature decreases in the order: (1) Cadmium, Tin (2) Zinc (3) Magnesium (4) Gold, Aluminum, Silver (5) Copper (6) Nickel. Recovery in these single crystals does not signify recrystallization, which, however, may be expected to accompany the recovery process at high (hot working) temperatures when, with increasing deformation, crumpling or nonuniform distortion of the crystal becomes too severe to permit a reversion to the unstrained condition without complete reorganization of the grain structure. This condition is rapidly attained in polycrystalline material, which recrystallizes even after a small amount of deformation. Such inequalities of deformation exert only a secondary influence on the amount of strain hardening and at a temperature of full recovery the occurrence of recrystallization does not appear to add materially to the softness attainable in the simple recovery process. From the above point of view, it is evident that the metals of Fig. 2 exhibit a decreasing tendency to soften or recrystallize after cold work in the order stated; that cadmium and tin would recrystallize at ordinary temperature, zinc and magnesium at not greatly elevated temperatures, and the others at successively higher temperatures. The effective temperature of hot working would also increase in this order but in a commercial operation would have to be determined by trial.

The following table gives temperatures of recrystallization after severe cold deformation, and favorable hot rolling temperatures of the ordinary commercially pure nonferrous metals.

Metal	Effective Softening Temp., °F. After Severe Cold Deformation (Approx. Complete Softening After 1 hr.)	Best Approx. Hot Rolling Temperature, °F. (For Softness) ^a
Lead	Approx. room temp.	Somewhat above room temp.
Tin	Approx. room temp.	Somewhat above room temp.
Zinc	200 ¹⁵	350
Magnesium	Between 200 and 400 ²	650 ¹⁶
Aluminum	525 ¹⁷	950 ¹⁸
Copper	700 ¹⁹	1550 ¹⁹
Nickel	1400 (max.) ²¹	2200 ²⁰

^aThis means in general the highest temperature for satisfactory operation. Special requirements of mechanical properties are met by rolling at lower temperatures.

Soldering (Soft Solders)*

Scope—The use and application of alloys such as lead-tin, lead-tin-cadmium, and others are discussed in this article. Attention is given to varieties of metals which can be soldered, types of fluxes and methods of application.

Definition—The alloys mentioned are generally referred to as soft solders, thus distinguishing them from hard solders (brazing solders and silver solders), which are described on page 1210. The term soft solders in this discussion is restricted to alloys that are fusible at temperatures below 700°F., whereas the hard solders are fusible at or above 1300°F. Unfortunately there appear to be no satisfactory solders, with high ductility and strength, that melt between 700 and 1300°F. One of the distinctions between a soldered joint and a welded joint is that in the former, the metals to be joined are not heated to their melting points. Consequently one of the requisites for a solder is that its melting point must be lower than that of the metals being joined.

Materials Soldered—Solders are employed for joining cast or fabricated metals of various compositions. Principally these are: Iron, copper, nickel, lead, tin, zinc, and many of their alloys. Materials such as glass and porcelain may be joined by soldering after their surfaces have been coated with metal or metallized by metal spraying or other suitable processes.

A.S.T.M. Standard Solders—The following compositions of lead-tin alloys have been designated as standard in A.S.T.M. Standard Specifications for Solder Metal, B 32-21 (A.S.T.M. Standards, 1933, pt. I, Metals, p. 817):

Grade No	Tin, %	Lead Approx., %	Antimony Max., %	Copper Max., %	Zinc and Aluminum, %	Other Impurities Max., %
Class A						
0	63.00	37.00	0.12	0.08	None	0.10
1	50.00	50.00	0.12	0.08	None	0.10
2	45.00	55.00	0.12	0.08	None	0.10
3	40.00	60.00	0.12	0.08	None	0.10
4	37.50	62.50	0.12	0.08	None	0.10
5	33.00	67.00	0.12	0.08	None	0.10
Class B						
1	49.25	50.00	0.75	0.15	None	0.10
2	43.50	55.00	1.50	0.15	None	0.10
3	38.00	60.00	2.00	0.15	None	0.10
4	35.50	62.50	2.00	0.15	None	0.10
5	31.00	67.00	2.00	0.15	None	0.10

The permissible variation plus or minus in the percentage of tin shall not be over 1% of the tin contents specified in Section 4.

The above compositions have been approved as standard by the American Standards Association. The S.A.E. Specifications No. 1, 2 and 3 practically conform to these standards. Other soldering alloys are given in Table I.

Sweating Solders—Sweating solders usually vary between 37.5:62.5 and 50:50 tin-lead. The popular composition is 40:60 and 45:55. This is a trade designation which means the per cent tin by weight is placed first and the lead second.

Fundamentals—While it may not be essential for a solder to alloy with the metal surfaces where applied, it appears desirable for it to do so. For good soldering work these rules must be followed:

- (1) The metal surfaces to be soldered must be clean and free from foreign matter and objectionable grease.
- (2) The metal surfaces while soldering must attain a temperature above the solidus point of the solder.
- (3) The flux should be molten at temperatures below the solidus point of the solder so that it can avoid being entrapped in the solder in the joint.
- (4) All traces of corrosive fluxes should be removed with particular care after the joints have been made.

Preparation—Generally, the first step in tinning or soldering is a cleaning of the metals to be coated or joined. The operation may be mechanical as by scraping,

*This article was prepared by a subcommittee, the membership of which was: G. O. Hiers, Acting Chairman; W. A. Cowan, E. E. Schumacher, and W. H. Swanger.

This article was not revised for this edition.

filing, or rubbing with sand or emery paper. Usually the preliminary cleaning is accomplished by chemical action with pickling solutions of acid or alkali. Frequently, metal parts to be joined by soldering are made from tinned sheet or wire in order to facilitate soldering. It is often desirable to apply a coating of pure tin or solder metal to the surfaces of metal parts to be joined subsequently by soldering.

For practical purposes, it is generally necessary to use a flux when soft soldering. The chief functions of fluxes are to prevent oxidation of the surfaces or to dissolve such oxides that may be present on these surfaces while they are being heated to the soldering temperature. They should also be fluid at the temperature of molten solder and be so applied that by gravity, capillarity or other forces the solder can displace the flux at the joint made. Mild fluxes such as tallow, stearin, and rosin particularly prevent oxidation but are not effective in removing oxides already present. Zinc chloride, with or without the addition of ammonium chloride, acts both as an oxidation preventive and a scavenger. Zinc chloride has a melting point of 689°F. and its eutectic mixture with ammonium chloride (71% ZnCl_2 , 29% NH_4Cl) has a melting point of 354°F., fortunately just below the melting point

Table I
Additional Alloys for Soldering and Other Uses

Tin	Per cent Anti-mony		Cadmium	Melting Range in °F.		Uses and Comments
	Lead			Liquidus	Solidus	
5	95			595	555	For coating and joining metals. For "high" temperatures.
10-20	90-80			580-545	500-361	For coating and joining metals. For "high" temperatures.
15-35	85-65			565-490	361	Low grade solder. For filling dents in automobile bodies.
37.5	60	2.5		435	367	Wiping solder for joining lead pipes and cable sheaths.
38-40	62-60			462-460	361	Wiping solder for joining lead pipes and cable sheaths. For automobile radiator cores and heating units.
45	55			437	361	For automobile radiator cores and roofing seams.
50	50			421	361	For general purposes. Most popular of all.
60	40			376	361	"Fine solder." For general purposes but particularly where the temperature requirements are critical.
95		5		464	450	For electrical work and copper tubing joints.
23	68		9	455	294	Wiping solder.
50	32		18	293	293	For fusibility, safety devices, and mounting micro specimens.
19	31		(50 Bi)	201	201	For fusibility, safety devices, mounting micro specimens, and fire prevention devices.
13	27		10 (50 Bi)	158	158	For fusibility, safety devices, and mounting micro specimens.
			95 (5 Ag)	734	639	For "high" temperatures.
			50 (50 Zn)	619	508	" "
			82.5 (17.5 Zn)	508	508	" "

The above solders and their uses are mentioned as typical. The classifications are informative and not complete or restrictive.

of the eutectic alloy, 62% tin, 38% lead. Therefore the zinc chloride-ammonium chloride eutectic mixture is desirable for use with the lead-tin eutectic solder (62% tin, 38% lead) when the latter is to be applied at a temperature just above its melting point. The ordinary flux solution is zinc chloride made by dissolving zinc in muriatic (hydrochloric) acid. A popular paste flux contains about 75% petroleum jelly, 20% zinc chloride, and 5% ammonium chloride with a small amount of water as an emulsifying agent. It is manufactured and sold by several companies.

Methods of Application—Most common metals and their alloys can be readily joined with solder. The method of application of solder to the metals to be joined varies according to the character of the metals, their position, the size of the parts to be joined, the speed with which the operation must be completed, and the shape, tensile strength and appearance required by the finished work. In every case, the

surfaces to be soldered must be brought to the melting temperature of the solder. The necessary heat is secured:

1. By repeatedly pouring the molten solder over the surfaces to be joined as in the wiping method; 2. By the use of the soldering iron or soldering copper; 3. By the use of blowtorch or electric arc; 4. By solder bath; 5. By sweating; 6. By spraying; and 7. By fusion of applied paste composed of atomized solder mixed with flux.

1. Wiping Methods—For joining sections of lead pipe, or of lead pipe with brass, bronze, or copper fittings with solder, or the joining of lead covered electrical cables using a lead sleeve, the wiping method is used. This method requires a high degree of skill and practice. The solder in a semiliquid state is poured slowly, and carefully distributed over and beyond the top and sides of the joint, which is being prepared, in order to furnish adequate heat for producing a good joint. Being in a fairly fluid condition, some of the solder drops off the joint onto the cloth which the workman holds under the joint. This dropped solder is pressed up against the bottom of the joint and the whole mass of hot solder is manipulated until every part of the joint is raised to a proper or "sweating" temperature, which insures a perfectly tight contact all-around. When this heat is attained, the pasty solder is shaped and rounded with the wiping pad, and all excess solder is wiped off as the joint slowly cools and the solder hardens.

Where the location prevents the use of a tool or mechanical device for joining lead pipes when soldering, the wiping method is used. The same method is employed in soldering joints to telephone cable sheathing for uniting a covering or sleeve which encloses connections of conductor wires. These joints must be capable of convenient reopening.

When joints are large, of a convenient shape, and are made by pouring from ladles, excellent adherence and soundness can be obtained by repeated pouring until sufficient heat is applied to properly form the joint. The excess solder in semi-solid form is wiped off upon subsequent cooling.

In wiping joints stearin in stick form is sometimes used for fluxing. Plumbers get some flux (tallow or lard oil) from the wiping cloth.

The wiping solders used in this country for making joints in pipes or for cable sheathing contain predominately 58-63% lead, the balance tin, although some users prefer the addition of up to 2% antimony (in filling joints in automobile bodies, an alloy is used somewhat as a wiping solder and usually contains about 30% tin and 70% lead). These alloys have an extended solidification range of about 140°F. and contain a considerable quantity of eutectic. The combination of these two factors makes possible the wiping of joints.¹ The use of cadmium substituted for some tin in the alloy has been thoroughly discussed in an article by Schumacher and Basch.²

2. Use of a Soldering Tool—A soldering tool is sometimes referred to as a soldering copper and sometimes as a soldering iron. It is usually copper, even when called an "iron". Before it can be used efficiently the iron must be "tinned" or coated with solder and maintained in a clean condition.

The tool is used in soldering sheet metals together where the sheets are either lapped or locked together and present a surface over which the soldering tool may be drawn.

The tool is heated to a temperature sufficient to quickly melt the solder, and is drawn along the edges to be joined at such a rate that the momentary high temperature of the edges together with the quickly molten state of the solder allows the formation of a tight waterproof seal. The soldering iron is also used in other work where there is a fire hazard and the use of a flame or molten solder poured over the surfaces is prohibitive.

Galvanized iron sheets and copper sheets used for roofing are generally soldered by means of the iron. Terne plate and tin plate are often similarly soldered.

3. Use of a Blowtorch—Where the metals to be joined or soldered are not large enough in diameter or rigid enough to permit the use of the wiping method or are not flat surfaces in position for the use of soldering copper, soldering is accomplished by playing the flames of a gasoline, kerosene, or alcohol blowtorch directly on the surfaces and then applying the solder cold in bar or wire form of appropriately small cross section. The heated surfaces melt the solder, excess solder being removed by wiping off before complete solidification. This method is in common usage by electrical workers in soldering wire joints and sweating on lugs.

4. *The Solder Bath*—Where the parts to be soldered are too numerous or too small for the use of the methods previously described the soldering is done by means of a molten bath.

The soldering of automobile radiators is a good illustration of this procedure. The radiator parts (cores) assembled into frames and therein tightly clamped have their ends dipped into a solder bath which is just deep enough to give the required depth to the joint. For making up the bath the solder may be purchased in the form of slabs weighing from 15-35 lb. Popular compositions for the bath are 50:50 and 40:60 tin-lead respectively, although more, and also less, tin-rich alloys are used by some manufacturers.

The soldering of tin cans is another good example. The cans are carried through the bath by a chain belt over a track which causes the cans to revolve. The track holds the cans at an angle of 45° so that the solder in the bath touches about ¼ in. of the bottom and side of the can thus making the joint. In a modern machine 300 cans per minute may be soldered in a single stream or procession.

5. *Soldering by Sweating*—The sweating process has been found best where a large number of metal objects are to be soldered with great rapidity and when they are of uniform size allowing the use of automatic machinery. Round tin cans, in addition to bath soldering, are also often sweat soldered and provide a good example of the method. The cans, mechanically assembled by forming and then crimping on heads and bottoms are carried on a moving chain belt over tracks which causes them to revolve while passing under a series of gas jets. The heated cans then pass under tubes which feed the correct amount of wire solder per can to the proper locations on the cans. The solder immediately melts on the heated cans and flows or sweats into the crimped joints, making securely soldered and air tight seams.

Other Methods—In soldering many specialties the usual soldering methods are often modified or combined and special tools devised to fit special conditions. However, no new principles are involved in any of these special shop practices.

Working Heat and Fluxing—A pot of solder should never be raised much beyond the necessary working temperature. On big work, where much heat is required to bring the metals to the proper temperature for efficient soldering, it is better practice to use a large pot carrying a large charge of solder at about the usual soldering temperature rather than to use a small pot and raise the temperature of the solder unusually high.

As the temperature of the molten solder is raised, the metal exposed to the action of oxygen in the air is oxidized unless protected by a hard soldering flux such as powdered borax, charcoal, and soda. When the molten solder is overheated in the air more tin than lead is lost proportionately because of somewhat preferential oxidation. If it is necessary to heat the solder excessively for any reason (as when a pot of solder has to be carried a relatively long distance), the metal should be covered with a hard soldering flux, as before mentioned. Stirring and skimming a pot of overheated solder are not recommended because of excessive loss by oxidation.

Upon solidification of a considerable quantity of 50:50 or similar solder, the primary crystals of lead sink to the bottom of the melting pot due to their greater density and permit the lead-tin eutectic to segregate toward the surface. To insure uniformity of composition of the solder, the alloy must be thoroughly stirred after melting and the temperature maintained above the complete liquefaction point (liquidus temperature) of the alloy.

In the consideration of fluxes attention should be directed to the kind of metals to be joined and their massiveness. Ordinarily it takes more heat to solder iron or steel than is required for soldering lead. Whenever a soldering iron is used, the heating is localized and the heat may be conducted away rapidly, consequently the iron must be exceptionally hot when the article is not preheated. In such cases, the use of rosin as a flux would be unsatisfactory since this material carbonizes at the higher temperatures thereby preventing rather than aiding soldering. When soldering large pieces of metal together, it is nearly always desirable to pre-tin parts individually before assemblage for soldering. This facilitates the soldering and makes stronger joints. Preheating is sometimes desirable. Before soldering cast iron the use of a cold pickling bath of 5% hydrofluoric acid is recommended.^a

Pastes or powders composed of pulverized tin or solder mixed with flux are on

the market and used to some extent. Tubular solder wire with a core consisting of rosin or other flux is quite popular. Adequate amounts of solder should be used in joints but economy demands no more than enough. To attain this end more expensive solders containing more tin are sometimes used because they flow better and less is required. To aid the consumer in the economical use of solder, soldering materials in suitable forms and of suitable dimensions are marketed by manufacturers. Some of the forms obtainable are tinner's bar, triangular bar, meter bar, ingot, wire in spools or in segments, drops, capping bar, slabs, powder, and tape, or ribbon.

The time required in making a good soldered joint may be extremely short. While prolonging of the period of time in which the solder is molten in a joint may increase the amount of alloying, the effect is generally not considered beneficial. When soldering copper, it is advisable to use a temperature below 752°F. in order to prevent the formation of the brittle copper-tin compound Cu_3Sn which, when present, tends to reduce the strength of a joint.

Mechanical Properties—Nightingale's tests¹ show 0.003 in. for a desirable thickness of a solder film on copper and 0.005 in. on steel. Crow⁴ previously indicated that the thinner the solder film the stronger the joint.

The Bureau of Standards⁵ investigated seams for copper roofing. It was decided that lap seams should be at least $\frac{3}{4}$ in. wide. For such a seam the maximum safe load was placed at approximately 350 lb. per in.² of seam area. The corresponding load for $\frac{1}{2}$ in. pre-tinned flat lock seams was 375 lb. per in.² of seam area. A 50:50 solder was used for the tests.

For automobile radiator cores of the honeycomb type 40% tin, 60% lead solders have been favored because of their supposedly greater vibration-fatigue resistance. Data for endurance limits are not available.

Tests have shown that tin-lead alloys containing only 3-8% tin have better strength at 302°F. than the richer tin alloys.

A 5:95 tin-lead alloy has found some popularity for use in joints maintained at elevated temperatures.

Owing to the fact that solder is frequently used to join metals stronger than itself it is often good policy to reinforce seams by crimping, interlocking, riveting, or bolting before soldering.⁶ Thus a joint can be made stronger by relieving the solder of the load, and making the major function of the solder that of hermetically sealing the seam.

Miscellaneous Notes—Aluminum may be soldered with lead-tin alloys or better with tin-rich alloys that contain considerable zinc. One method is to rub the aluminum surface beneath molten solder thereby piercing the oxide film and permitting alloying of the solder with the aluminum^{8, 10}. Brazing or welding is often preferred to soldering of aluminum.

When soldering stainless steel, ample time should be allowed for the flux to act properly before applying the solder.

For soldering zinc or galvanized iron, the presence of antimony in the solder is undesirable, because antimony forms an infusible compound with zinc, thereby spoiling the flow of the solder.

Brazing and Related Joining Methods*

Introduction—Brazing is a term that is usually applied to a process for joining metals with alloys of copper and zinc which melt at temperatures appreciably below the melting points of the metals to be joined. The common brazing or spelter solders are composed of approximately equal parts of copper and zinc and melt at temperatures from 1600-1650°F., depending upon the relative proportion of the two metals. Many of the fundamental principles involved in the use of these alloys are similar to those governing the use of silver solders which have a lower range of melting points and bronze welding rods which have a higher range. The scope of this article has, therefore, been extended to include alloys having melting points ranging from approximately 1200-2250°F.

Preparation of the Joint—Clean and properly fitted joints are prerequisite to satisfactory bonding. All surface scale or oxides should be removed either by chemical or mechanical means. Oil, grease, and dirt of any description interfere with good work.

The allowable clearance between the surfaces to be joined will vary according to the alloy used, type of joint, method of heating and the metals joined. With free flowing brazing alloys such as silver solders, closely fitted joints with maximum clearance of a few thousandths of an inch will give the best results. When bronze welding rods are used it is common practice to make a "V" joint and fill the joint with successive layers of the brazing alloy.

Fluxes—The temperatures required for brazing cause a rapid oxidation of the surfaces of the joint if exposed to the air during the heating. A thin film of oxide will prevent proper bonding and the surfaces should be protected with a salt or combination of salts that will help to prevent oxidation and dissolve or flux any oxides that may form.

Common borax is a thin fluid at 1400°F. and at this temperature unites quickly with the oxides of most metals.

It contains approximately 47% water of crystallization, which is driven off when heated, thus causing the flux to "bubble". Fused borax is, therefore, preferred by some workmen and if used as a paste, it should be mixed with alcohol because the fused borax quickly takes up the water and becomes common crystalline borax again.

Boric acid is sometimes used alone as a flux but generally in combination with borax or other salts. It is not as active as borax for dissolving oxides of metals but has the property of spreading over the surface at a relatively low temperature and thus protects the surface from oxidizing. Combinations of borax and boric acid are extensively used, particularly with brazing alloys at temperatures above 1500°F.

The alkali bifluorides in combination with borax and boric acid are used as fluxes when joining metals having refractory oxides such as chromium in stainless steels. The potassium salts are more effective than the sodium and by varying the proportions of the salts enumerated in this and preceding paragraphs a wide range of fluxes can be produced to meet the different conditions encountered in brazing work.

There are many satisfactorily prepared fluxes available, some of which may contain phosphates or halogen salts, but regardless of the particular composition selected it is most important that it be applied in such a manner as to insure that all oxide films will be removed. Moreover, the flux should be a thin liquid at the brazing temperature in order to prevent inclusions which will subsequently give trouble. Both the surfaces of the joint and the brazing alloy should be protected with flux if the best results are to be obtained.

The flux may be used dry, in paste form, or by means of hot saturated solutions. When used in paste or hot solutions, it is advisable to brush the flux over the surfaces because a more uniform coating can be obtained and there is less chance for bare spots that will oxidize during the heating. When the brazing alloys are in granular form it is common practice to mix the flux with the alloy before spreading along the joint. Strip, wire, and rods can be coated before using or by dipping the end into a small can of flux paste just before applying to the joint, or by heating the rods and sprinkling the dry flux on them.

*This article was prepared by a subcommittee the membership of which was as follows: R. H. Leach, Chairman; J. R. Freeman, Jr., and Samuel Epstein.

Methods of Heating—The four principal methods of supplying the heat necessary for brazing are: Dipping the parts into a bath of the molten alloy, called dip brazing; heating by torches; furnaces; and by electrical resistance devices of various types.

In dip brazing the alloy is melted in a refractory container and covered with flux to prevent oxidation. The parts to be brazed are assembled in a suitable jig to hold them in position and dipped into the molten alloy. The size of the bath of the metal must be in proper proportion to the work. Heating may be done by any of the methods used with pot furnaces.

Another type of dip brazing which can be used is the salt bath type of furnace in which the articles to be brazed are immersed in the bath of molten salt, the parts having been previously assembled and the solder applied to the joint before immersing in the bath.

Different types of torches are used including air-gas, oxygen-gas, and oxy-acetylene. The high temperature of the oxy-acetylene flame allows rapid heating which is an advantage. A neutral or slightly reducing flame should be used in most cases, although for some types of bronze welding a slightly oxidizing flame is recommended.

Furnaces are used quite extensively for certain types of brazing. The brazing alloy is applied either along the joint or by inserts and the assembled parts introduced into the furnace. Furnaces with nonoxidizing atmospheres are preferable but if the joint is properly protected with flux, good work can be done in ordinary furnaces. The furnace should be large enough to allow the heating to be done rapidly and the temperature of the furnace should be considerably above the melting point of the brazing alloy.

The electrical resistance method is used on small parts or in those cases where a thin sheet of the brazing alloy can be inserted in the joint. It has the advantage of localizing the heat and works quickly.

Types of Brazing Alloys—The selection of the best brazing alloy depends upon many different factors. As the alloy must melt at a temperature below the melting points of the metals to be joined, the melting points of brazing alloys give a basis for three broad classifications:

Class I. Silver solders—Alloys having melting points ranging from 1200-1600°F.

Class II. Brass and nickel-silver brazing alloys—Alloys having melting points ranging from 1600-1700°F.

Class III. Copper alloy welding rods have melting points ranging from 1600-2250°F.

A general description of these three groups of alloys follows:

Table I
Silver Solders from A.S.T.M. Specification

Grade No.	Silver, %	Copper, %	Zinc, %	Cadmium, %	Impurities, % Max.	Melting Point, °F.	°C.	Flow Point, °F.	°C.	Color
1	10	52	38	a	0.15	1510	820	1600	870	Yellow
2	20	45	35	a	0.15	1430	775	1500	815	Yellow
3	20	45	30	5	0.15	1430	775	1500	815	Yellow
4	45	30	25	nil	0.15	1250	675	1370	745	Nearly white
5	50	34	16	nil	0.15	1280	695	1425	775	Nearly white
6	65	20	15	nil	0.15	1280	695	1325	720	White
7	70	20	10	nil	0.15	1335	725	1390	755	White
8	80	16	4	nil	0.15	1360	740	1460	795	White

*The addition not to exceed 0.50% of cadmium to assist in fabricating Grades 1 and 2 shall not be considered as harmful impurity.

Solders of Grades 1, 2, and 3 are suitable for brazing purposes which require a solder that flows more readily than the ordinary copper-zinc brazing solders. Grades 4 and 5 flow freely at a still lower temperature and are recommended for use where strong joints are required and in such cases where heating to a sufficiently high temperature to flow Grades 1, 2, or 3 would be injurious to the article being soldered. Grades 6, 7, and 8 are higher grade silver solders and are recommended for special cases where a high degree of malleability and ductility is required.

Silver Solders—Ternary alloys of silver, copper, and zinc in varying proportions have been used for many years as brazing alloys and are commonly called silver solders. The addition of silver to binary copper-zinc alloys lowers the melting point and a series of alloys can be made that will flow freely at temperatures from 1250-1600°F. In general, alloys having lower melting points contain relatively less zinc and high silver. Table I gives a list of the A.S.T.M. standard silver solders with the approximate melting points, flow points, and colors of grades.

Cadmium and tin are sometimes added to the ternary silver-copper-zinc alloys. Nickel, manganese, and chromium are also used but the standard alloys given in the A.S.T.M. specifications have been found to meet most of the requirements.

Silver solders are extensively used on practically all nonferrous metals and alloys and on steels and iron because of their strength, low melting points, free flowing properties, and resistance to corrosion. The strongest joints are made with small clearances, not over three or four thousandths of an inch for best results. Joints will stand severe shock and vibrations.

Borax or combinations of borax and boric acid are satisfactory fluxes except in the case of stainless steels when the addition of one of the alkali bifluorides or a halogen salt will prove beneficial. Fluxes that are fluid below 1400°F. are less likely to give trouble from inclusions, and particularly with the low melting point silver solders a great deal of the advantages in their use are lost if excessive superheat is required to keep the flux sufficiently fluid. By proper design and fitting of the joint, such a small amount of silver solder is required that although the cost of the silver solder may seem high, as compared to base metal solders, it has been found by experience that the cost of the finished joint will compare favorably with the base metal alloys in many cases.

The silver-copper-phosphorus eutectic melts at 1190°F. and a self-fluxing alloy* containing about 2.5% less phosphorus than the eutectic is used for brazing copper, brass and other nonferrous alloys. This alloy flows freely at a temperature of 1300°F., which is a most desirable property. Properly fitted joints have high tensile strength and are malleable. It can be rolled into thin gage sheet and drawn into fine wire. With brass and other alloys only a small amount of flux is required. Borax can be used as a flux but special fluxes which are more fluid than borax at 1300°F. are preferable.

In general, the use of silver solders should be considered where the higher temperatures required for other brazing alloys might cause excessive grain growth or damage to the metals to be joined and where strong ductile joints are necessary. They can be obtained in all sizes of wire and gages of sheet thus making it possible to obtain and apply them in the most convenient and economical form for use. They are also supplied in filings of different sizes.

Table II
Special Silver Solders

Grade No.	Silver, %	Copper, %	Zinc, %	Cadmium, %	Lead, %	Phos	Melt Point, °F.	Flow Point, °F.

³Proprietary Alloy, "Sil-Fos," Handy & Harman.

Solders No. 1-4, inclusive, are used in those cases where strength is not an important factor but their higher melting range insures a greater margin of safety against failure at slightly elevated temperatures. In general, their other physical properties are more comparable to the standard soft solders. Solder No. 5 has the characteristics of the standard silver solders and strong joints can be made on nonferrous and ferrous metals and alloys, including stainless steel. The advantages of this solder are its low flow point and the strength of joint.

Brass and Nickel-Silver Brazing Alloys—Brass brazing alloys, quite generally known as "spelter solder" or "brazing solder" are alloys of copper and zinc in about equal proportions with smaller amounts of tin and nickel. These brazing solders are generally applied in powder or granulated form and melted by heating the several parts to be brazed to just about the melting point of the brazing solder, at which temperature the solder becomes fluid and runs readily between the contacting surfaces, alloying and bonding them together in a similar manner to soft and silver soldering. Dip brazing is also widely used. In this method the parts to be brazed are dipped into a molten bath of the brazing alloy, the parts having previously been suitably clamped together in the desired relative positions.

Table IV
Representative Copper Alloy Welding Rods

Alloy No.	Composition		Manganese	Copper	Melting Point, °F.	Remarks—Color, Name and Use
	Zinc	Tin				
1	38-43	0.50-1.50	Remainder	1625	Strong yellow bronze for general oxy-acetylene welds on steel, cast iron, copper, brass, bronze, and nickel alloys. Tobin bronze. Strength of approximately 50,000 psi. in tension. Distinctive yellow color.
2	38-43	0-1.5	0.05-0.75	Remainder	1600	Manganese bronze, quite similar to above except it is harder and more wear resisting than the Tobin bronze. Yellow bronze.
3	Silicon 3-4	0.75-1.25	Remainder	1860	Silicon bronze, Everdur. High strength of approximately 50,000 lb. Applicable by oxy-acetylene torch to Everdur, copper, brass, bronze, nickel alloys and by the electric arc to Everdur, copper, bronze, and nickel. Pale red, characteristic bronze.
4	Tin 2-10	Phosphorus 0.03-0.40	Remainder	1950-1830	The familiar phosphor bronze. Good strength, 40,000 psi., excellent wear resistance for higher tin and phosphor proportions. More frequently applied by means of the metallic or long carbon arc. Applicable to copper, bronze, brass, steel, and nickel alloys. Copper red to characteristic bronze color.
5	23-27	Nickel 15-19	Manganese 0.05-0.15	Remainder	1980	Wrought nickel silver. Nickel white color. Moderate strength 40,000 psi. Applicable only by oxy-acetylene or carbon arc torches. Used principally in welding similar base metals.
6	Nickel 29-31	0.05-0.15	Remainder	2235	Cupro-Nickel 70-30. Nickel white color. Good strength, 50,000 psi. Applicable to white metals by oxy-acetylene torch or metallic arc. Covered electrode necessary for latter.
7	Phosphorus 0.03-0.09	Remainder	1980	Deoxidized copper. Used principally for welding copper by means of the oxy-acetylene torch. 28,000 psi. Copper red color.

There are many variations of compositions which may be used but the compositions given in Table III are quite representative of all types in common use. The general properties and uses are also indicated. The first two compositions listed correspond to A.S.T.M. Standard Specification B64-28.

Brazing solders are supplied in different grades, classified according to size and general shape of grain, known as "round grain", "long grain", and "lump". The latter is used primarily for dip brazing.

Fluxes for brazing alloys are in general the same as used for silver solders. Common borax used dry or mixed with water is used quite often but the water free powdered fused borax is preferable as it does not "crawl" away from the heat. Mixtures of boric acid and fused borax are also quite satisfactory. The fused borax fluxes should be mixed with commercial alcohol (water free) rather than water when a paste is desired.

The brazing operation may be carried out by heating with air, oxy-acetylene, oxy-hydrogen, or compressed air and gas torch, by furnace heating, or by carbon electric resistor placed against the work. In the dip process the heat comes from the bath although preheating in a furnace is often desirable.

In all except the dip brazing process the brazing alloy mixed with suitable amounts of flux is sprinkled or "painted" on the parts to be brazed before heating.

The phosphor-copper eutectic melts at approximately 1304°F. and contains 8.3% phosphorus. By lowering the phosphorus content to 7% or less, brazing alloys* are produced which can be used with copper and brass; the phosphorus in the alloy acting as a flux.

Copper Brazing is a term applied to the joining of steel when pure copper is used as the brazing alloy. The temperature must, of course, be above the melting point of copper (1980°F.). In copper brazing, the assembled steel parts with scraps of copper on the joints are most frequently placed in a furnace having a controlled hydrogen or other suitable atmosphere. Occasionally an oxy-hydrogen torch with excess hydrogen is resorted to.

Bronze Welding Rods—In addition to the two groups of alloys listed above, there is a third large group of ductile copper alloys which are, by reason of the welding methods employed in their applications, more properly termed welding rods.

These alloys are used: (1) where a moderately high strength (about 50,000 psi.) is required, (2) where good bearing or wear resistance is desired, (3) where the weld must possess some of the corrosion resistance characteristics of the base metal, or (4) where a color match is required, weld metal to base metal.

Welding Process—Though some of the yellow bronzes melt at a temperature only a few degrees higher than the 50:50 brazing alloys, the oxy-acetylene torch is quite generally used as a source of heat for welding rod and base metal.

With those welding rods which have little or no zinc in their make-up, the metallic or carbon arc may be used. The zinc from the yellow bronzes is volatilized too freely in the highly concentrated heat of the arc to admit of their being applied by the metallic or carbon arc.

Flux—Many good commercial fluxes for the high zinc bronzes are available. They are made up of various proportions of fused borax and boric acid.

These brazing fluxes are not entirely satisfactory for the silicon and the nickel alloys. An addition of sodium or lithium fluoride to the fused borax helps in the flowing of the silicon-copper alloys and the addition of a bifluoride to the fused borax base helps in preventing the formation of nickel oxide in the copper alloys.

In general, for connecting of cast iron, steel, copper, and nickel alloys where a color contrast is not objectionable, Alloy No. 1 in Table IV will be found most satisfactory. This alloy is without doubt the handiest and most nearly universal welding rod available for the repair shop and small manufacturer.

For high wear resistance surfaces Alloy No. 2, applied by the oxy-acetylene torch, or the 10% tin Phosphor Bronze, Alloy No. 4, applied by metallic or carbon arc, can be used.

For comparable corrosion resistance, select the welding rod which is nearest the composition of the base metal.

*Proprietary Alloy, "Phos-Copper," Westinghouse Electric & Mfg. Co.

Welding rod No. 3 is used for the most part in making fusion welds in a base metal of a similar composition by the use of the oxy-acetylene torch or the carbon or metallic arc. The base alloy is finding a wide application in the manufacture of hot water storage tanks and various vessels for the chemical industries.

Of the two white metals, Alloys No. 5 and 6, the former is used almost entirely on the nickel-silver alloys using the oxy-acetylene torch though it could be used on steel if the yellow of Alloy No. 1 were objectionable.

Alloy No. 6 is appropriate for use on the 70:30 Cupro Nickel base metal which is finding wide application in situations where a combination of strength and corrosion resistance is desired at elevated temperatures.

A word of caution should be given about the possibility of intercrystalline embrittlement of steel joints when brazing with brass or bronze brazing alloys. If the joint is heated above 2000°F. intercrystalline penetration of the brass into the steel may occur. For example, oxy-acetylene or arc welding of joints which have been brazed are likely to cause trouble and this practice should be avoided as far as possible.

The Aluminum Industry

By Junius D. Edwards*

Aluminum as an element has only been known about 100 years, and its commercial history is comprised within the last 50 years. It is one of the principal metallic products of the electrochemical industry.

Occurrence—The principal ore of aluminum is bauxite. Bauxite comprises the hydrated oxides of aluminum, $\text{Al}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ and $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$, together with associated impurities such as the oxides of iron, silicon, and titanium. Bauxite is produced by the weathering and alteration of aluminum silicate rocks, and is widely distributed the world around, usually in tropical and semitropical regions, where the weathering processes which have produced it have proceeded at an accelerated pace. At the present time, the principal supplies of bauxite come from France, the United States, Dutch Guiana, British Guiana, Hungary, Italy, and Jugo-Slavia. Bauxite is thus not a rare ore, and its principal value, when delivered in refined form for the electrolytic production of aluminum, lies in the transportation charges and chemical refining costs incident to its purification. The bauxites used for the production of aluminum contain about 55-65% alumina; it takes about 4 lb. of bauxite, therefore, to produce 1 lb. of aluminum. It has been estimated that there is enough bauxite in sight to supply the world with aluminum for the next 1,000 years.

Extraction or Refining Methods—In the electrolytic reduction of aluminum oxide, any impurities such as the oxides of iron, silicon, and titanium are reduced, along with the alumina. The alumina used is first refined, therefore, by removal of these impurities. It is essential to start with raw materials of the highest purity, and this includes not only the alumina but the carbon electrodes and the fused electrolyte employed in the process.

The Bayer process is almost universally employed for the purification of bauxite. In this process the bauxite is digested with caustic soda solution under pressure and the alumina dissolved out as a solution of sodium aluminate. The residue, known as red mud, contains the oxides of iron, silicon, and titanium, and is separated by filtration. Aluminum hydrate is separated from the solution of sodium aluminate by precipitation and is converted to the oxide, Al_2O_3 , by calcination.

The electrolytic reduction process is based on the discovery of Charles M. Hall, that molten cryolite dissolves alumina and that aluminum can be separated continuously from the molten solution at about 1000°C. by electrolysis. In operation, the electrolytic reduction takes place in large cells; they consist of a steel shell lined with carbon, forming an inner cavity in which the cryolite electrolyte is held. The carbon anodes, dipping into the electrolyte, introduce the current which separates the metallic aluminum electrolytically and provides the heat which keeps the bath liquid. Molten aluminum deposited on the bottom of the cell is withdrawn from time to time as it collects. This is the primary aluminum of commerce and will run in purity up to about 99.8%, depending upon the care and skill with which the raw materials have been prepared and the reduction process carried out. Aluminum of higher purity (up to 99.99%) can be produced by the Hoopes electrolytic refining process, in which aluminum is electrolytically dissolved from a molten aluminum-copper alloy anode and deposited in a layer of pure aluminum acting as cathode and floating on the molten electrolyte which separates the anode from the cathode layers. The production of a pound of aluminum requires about 10 kw-hr. of electrical energy, so that cheap electric power is essential for its commercial production.

Principal Products—The aluminum sheet of commerce, designated 2S by the principal producer, has a nominal purity of about 99.2%. It is, in fact, an alloy with small amounts of iron and silicon, and its strength is substantially increased thereby. Another commonly used wrought alloy, known as 3S, contains 1.25% of manganese. The principal elements used in the production of aluminum alloys are copper, silicon, manganese, magnesium, and zinc. Since the invention of duralumin and the discovery and explanation of heat treatment effects in aluminum alloys, a series of heat treatable aluminum alloys have been developed. They are frequently referred to as the "strong alloys of aluminum" and greatly extend the field of application of aluminum.

*Aluminum Research Laboratories, New Kensington, Pa.

Uses—Aluminum and its alloys can be worked and fabricated by the usual metal working processes such as rolling, stamping, spinning, drawing, extruding, and forging, and produced in the form of castings by the sand, permanent mold, or die casting processes. Except for magnesium and beryllium, aluminum is the lightest of the structurally useful metals. In the transportation field, it is not only the lightness of aluminum and its alloys, but the high physical properties obtainable by alloying and heat treating which make it suitable for light weight structures.

Aluminum has good electrical conductivity; volume for volume, its electrical conductivity is about 61% that of copper, and weight for weight, its conductivity is about 200% that of copper. High electrical conductivity, combined with good weather resistance and adequate physical properties, accounts for its use in over 700,000 miles of aluminum cable, steel reinforced.

Aluminum is also a good conductor of heat. This property is made use of in such varied applications as cooking utensils, and pistons and cylinder heads for internal combustion engines.

Aluminum is a good reflector for radiant energy throughout the spectral range, from ultra-violet through the visible range and into the infra-red. It is being employed in thin films on the reflectors of the most modern telescopes, is widely used for light reflectors in the illuminating industry, and its high reflectivity for infra-red radiation is giving it a unique field of usefulness for thermal insulation. As a practical light reflector, its usefulness has been extended by the Alzak process, which includes electrolytic brightening to develop maximum reflection, coupled with an electrolytic oxide coating to provide a glass-like, transparent, weather resistant and cleanable surface. In the thermal insulation field, aluminum foil,

Fig. 1—Primary aluminum produced in the United States and in the world, 1913-1936, compared with imports into the United States and with domestic consumption, exports, secondary production, and the trend of the average New York quoted price (No. 1 virgin ingot, 98-99%). Courtesy of Bureau of Mines, Minerals Yearbook, 1937.

with its high reflectivity for thermal radiation and its low radiating power or emissivity for the same type of radiation, gives to a structure comprising sheets of aluminum foil separated by air spaces, a high insulating effect.

Aluminum forms, in contact with moist air, a thin, impervious film of oxide which protects it against further attack. It can be electrolytically oxidized to give it a thicker oxide film of great hardness and resistance to corrosion. These oxide films can be colored by the absorption of dyes or by impregnation with inorganic pigments.

Aluminum has a high heat of combustion, and this affinity for oxygen is the basis of the Thermit welding process, where reaction between finely divided alumi-

num and metallic oxides, such as iron oxide, produces a molten ferrous alloy at a high temperature.

Another chemical use of aluminum is as a deoxidizer in the manufacture of iron and steel. Its affinity for oxygen is so great that it is used in producing gas-free steel ingot.

Aluminum in finely divided flake-like form, supplied either as aluminum powder or aluminum paste, makes an excellent paint pigment. Aluminum paint made with this pigment forms a durable and protective paint for both metal and wood. It is relatively impervious to moisture penetration; is opaque to sunlight, hides and covers well, and maintains this protection over extended periods, even under conditions of severe exposure.

Statistics—The uses of aluminum and its alloys are being expanded as research develops a sound basis of fundamental knowledge regarding its physical, chemical, and engineering properties. During the last decade, the applications of aluminum in the U. S. have been along the following principal lines:

Percentage of Aluminum Used in Various Industries

Transportation (land, air, and water) ..	38%
Electrical conductor	16%
Cooking utensils	14%
Machinery and electrical appliances.....	9%
Iron and steel metallurgy.....	8%
Building construction	4%
Miscellaneous foundry and metal working.....	4%
Chemical	2%
Food and beverages.....	2%
General miscellaneous	3%

Constitution of Aluminum-Chromium Alloys

By W. L. Fink* and H. R. Freche*

A few commercial aluminum alloys contain small amounts of chromium, but substantial amounts of chromium increase the liquidus temperature beyond commercial limits. Consequently, the extreme aluminum-end of the system is of greatest interest.

Fig. 1—Aluminum end of the Aluminum-Chromium Constitution Diagram.

of sodium hydroxide at 70°C. darkens the constituent. When etched with 0.5% hydrofluoric acid, the constituent is outlined but does not change in color.

Leon Guillet¹ studied aluminum alloys containing from 65-90% chromium. He observed the two intermetallic compounds AlCr and AlCr_2 in this concentration range. According to Hindrichs² aluminum and chromium form an intermetallic compound AlCr , which corresponds to 85.2% chromium. Goto and Dogane,³ in their paper on the aluminum-chromium alloys, suggested the intermetallic compound CrAl .

In a recent investigation by Fink and Freche⁴, on the aluminum-end of the aluminum-chromium diagram, alloys were used which contained 0.02% iron and 0.01% silicon and 0.01% copper. The results of the investigation are illustrated by Fig. 1. At the aluminum-end of the system, the intermetallic compound CrAl , which contains 21.60% chromium and 78.40% aluminum, was identified. At 661°C. a peritectic reaction occurs between CrAl and a melt, containing 0.41% chromium, to form a solid solution containing 0.77% chromium. The solid solubility decreases with temperature; and at 530°C. the saturated solid solution contains only 0.25% chromium.

In aluminum-rich alloys, the unetched chromium constituent appears gray when illuminated by the light from a carbon arc filtered through a 78A Wratten filter. A 10% solution of sodium hydroxide at 70°C. darkens the constituent. When etched with 0.5% hydrofluoric acid, the constituent is outlined but does not change in color.

Constitution of Aluminum-Copper Alloys

By E. H. Dix, Jr.* and H. H. Richardson†

The aluminum-rich alloys of the aluminum-copper system are of great commercial importance in both wrought and cast forms. The wrought alloys generally do not contain over 5% copper, although the cast alloys may contain as much as 12-15% copper. With further increase in copper content the brittleness of the alloys is too great to permit more than a few special commercial applications. Both the wrought and cast alloys are subject to improvement in strength and hardness by heat treatment.

Because of the commercial importance of the aluminum-copper alloys the constitution of this system has been the subject of a number of independent researches. At the aluminum end of the series an intermediate aluminum-copper solid solution forms a eutectiferous series with aluminum in which the eutectic alloy contains 33% copper and melts at 548°C. At the eutectic temperature 5.65% copper is soluble in solid aluminum and this amount decreases to less than 0.5% at room temperature. The susceptibility of the aluminum-copper alloys to improvement in strength by heat treatment depends on this decrease in solubility.

The diagram of Fig. 1 is according to the most recent work of Stockdale,¹¹ but modified in the composition range shown in the insert to agree with the investigation of Dix and Richardson.⁷ The present diagram of Stockdale differs, in the range shown, from an earlier diagram⁸ in that a solid solution region from 52.5-53.9% copper is shown in place of the intermetallic compound CuAl₃. The more recent

Fig. 1—Aluminum-Copper Constitution Diagram (Stockdale, Dix, and Richardson).

type to improvement in strength and hardness by heat treatment.

The solubility data shown in the following tabulation and the insert of Fig. 1 were arrived at by microscopic examination of alloys of extremely high purity, which had been annealed for long periods of time:

Saturation Limit of Copper in Solid Aluminum According to Dix and Richardson

Temperature, °C.....	200	300	350	400	450	500	548
Per cent copper.....	0.50	0.70	1.00	1.50	2.60	4.10	5.65

These results are in fair agreement at the eutectic temperature with the result obtained by Rosenhain⁹ at the National Physical Laboratory and at 300°C. with that of Merica¹ at the U. S. Bureau of Standards. They also agree with the results obtained by Ohtani and Hemmi¹⁰ who used electrical resistivity measurements for a limited temperature range of 420-520°C. The solubility at 200°C. was obtained on chill cast specimens annealed at that temperature for two weeks subsequent to

*Chief Metallurgist, Aluminum Research Laboratories, New Kensington, Pa.

†Metallurgist, Aluminium Limited, Geneva.

a homogenizing treatment of 11 days at 540°C. The more recent results of Stockdale for the limited range from 460-530°C. are in agreement with the above values.

The θ phase, when it occurs in the light aluminum alloys, polishes slightly in relief and has a marked tendency to tarnish. However, if carefully polished it is clear and almost colorless, with a slightly pink tinge. Its most striking characteristic is the way in which it lights up in passing out of focus. A light etch with 0.5% hydrofluoric acid leaves this constituent clear with a well defined boundary. It is colored brown or black by immersion for 40 sec. in 25% nitric acid at 70°C., followed by quenching in cold water.

The solid solution of copper in aluminum has been shown by X-ray analysis^{4, 9, 10} to have a face centered cubic lattice similar to that of pure aluminum. Solution of copper is effected by simple substitution with a contraction of the lattice. The θ phase or the so-called CuAl, has been shown by X-ray analysis^{4, 9} to have a body centered tetragonal structure with an axial ratio of 0.805.

See page 1342 for a discussion of the copper end of this diagram.

Constitution of Aluminum-Iron Alloys

By E. H. Dix, Jr.*

Iron is always present in aluminum of commercial purity and even the highest purity electrolytically refined aluminum (99.95% Al) contains visible particles of an iron constituent. In the commercial aluminum alloys, iron is often found in complex constituents containing aluminum and one or, perhaps, more of other elements such as silicon, manganese, or copper. Two ternary aluminum-iron-silicon constituents have been definitely identified.

Fig. 1—Aluminum-Iron Constitution Diagram (Gwyer, Phillips, and Dix).

In aluminum substantially free from other elements, iron occurs as the aluminum-iron compound, FeAl_3 . As shown by the diagram, Fig. 1, aluminum and FeAl_3 form a simple eutectiferous series. Reliable investigations have placed the eutectic concentration at 1.7-2.5% iron and the temperature at 648-655°C. These differences are probably caused by variations in the purity of the aluminum used and the pronounced tendency of the alloys to undercool.

The figures indicated in the insert, showing the eutectic region, of Fig. 1 were obtained on aluminum of very high purity (impurities other than iron less than 0.03%). The iron content of the eutectic was obtained by chemical analysis of very slowly cooled specimens, which were shown by microscopic examination to have a eutectic structure. However, by rapid cooling from a high temperature a fine structure having the appearance of a eutectic was found with iron as high as 3.5%. The eutectic temperature was determined from a consideration of a number of heating and cooling curves of the same high purity material.

FeAl_3 is practically insoluble in solid aluminum, although fine particles of eutectic FeAl_3 exhibit marked coalescence after an extended annealing just under the eutectic temperature.

In a properly polished specimen particles of FeAl_3 appear bright with a slightly purple tinge. Swabbing with 0.5% hydrofluoric acid slightly attacks the aluminum solid solution and so removes any slight surface flow, and if not carried too far the FeAl_3 retains its characteristic bright purplish color.

FeAl_3 is colored black by 30 sec. immersion in a 20% solution of H_2SO_4 at 70°C., followed by quenching in cold water. However, the iron-silicon-aluminum constituents are also attacked by this reagent, although the appearance after etching is different. A similar procedure with 25% HNO_3 is useful in differentiating between these constituents.

Constitution of Aluminum-Manganese Alloys

By E. H. Dix, Jr.,* W. L. Fink,* and L. A. Willey*

Introduction—Manganese is used in relatively small amounts in a number of commercial aluminum alloys. In these alloys, the manganese occurs in a complex aluminum-manganese constituent in which atoms of iron or other elements have replaced a part of the manganese atoms. Chemical analysis of such constituents separated from aluminum-iron-manganese alloys has shown as much as 1 atom of iron to 2 atoms of manganese. The presence of iron, even in small amounts, in the constituents greatly alters their solubility. Consequently it is very difficult to prepare alloys of sufficient purity to be classed as binary alloys. Most of the results found in the literature were obtained from alloys that contained a considerable quantity of silicon, iron, and copper as impurities, and, therefore, really apply to complex systems.

Constitution Diagram—Krings and Ostmann¹ in their work on the aluminum-copper-manganese alloys assigned the formula $MnAl_4$ to the compound at the aluminum end of the binary system. They found the eutectic between this compound and aluminum at 649°C. and 3% manganese. Rassow² found a eutectic temperature of 650°C. He assigned the formula $MnAl_4$ to the compound at the aluminum end of the system and interpreted a thermal arrest occurring at 670°C. as a polymorphic transformation of that compound. Bradley and Jones,³ through X-ray analysis of annealed aluminum-manganese alloys, also concluded that the aluminum-rich compound was $MnAl_4$. The diagram of Ishiware⁴ shows that a compound $MnAl_4$ reacts with the melt at 670°C. to form the compound $MnAl_6$. Bosshard⁵ determined the solid solution range at the aluminum end of the system but his values are lower than those for binary alloys because his samples contained large amounts of impurities.

Fig. 1—Aluminum-Manganese Constitution Diagram (Dix, Fink, and Willey).

In a recent investigation by Dix, Fink, and Willey⁶ alloys were used which contained less than 0.01% each of iron, silicon, and copper. It seems probable that such small amounts of impurities would not substantially alter the results and that the diagram shown in Fig. 1 is a close approximation to the true binary diagram.

At the extreme aluminum end of the system the intermetallic compound $MnAl_4$, containing 25.35% manganese, forms a eutectic with an aluminum-manganese solid solution. This eutectic occurs at 1.95% manganese and 658.5°C. The solid solubility of manganese in aluminum decreases from 1.82% at the eutectic temperature to 0.36% at 500°C. The compound $MnAl_4$ decomposes at 710°C. to

*Aluminum Research Laboratories, New Kensington, Pa.

form the compound $MnAl$, containing 33.7% manganese and liquid aluminum containing 4.06% manganese in solution.

In aluminum-rich alloys, the unetched constituent $MnAl$, has a flat gray appearance. A solution containing 1% sodium hydroxide etches this constituent to a blue gray color in about 10 sec. at room temperature. A 10% solution of sodium hydroxide at 70°C. etches the compound dark brown to black. When etched with 0.5% hydrofluoric acid, the compound is outlined, but does not change color unless iron is present, in which case the constituent turns brown or black.

Constitution of Aluminum-Nickel Alloys

By Wm. L. Fink* and L. A. Willey*

Several of the complex commercial alloys of aluminum contain nickel as one of the alloying elements. Although the pure binary aluminum-nickel alloys are not important from a commercial standpoint, a knowledge of the constitution of the system is a prerequisite for the study of the more complex commercial alloys.

Fig. 1—Aluminum-Nickel Constitution Diagram (Fink and Willey).

solid solution form a eutectic at 5.7% nickel and 640°C. The insert of Fig. 1 shows the solubility curve in detail. The limit of solid solubility decreases from 0.05% nickel at the eutectic temperature to approximately 0.005% at 500°C.

Although the solubility in the solid state is slight, the binary alloys containing a few hundredths of a per cent of nickel have relatively high susceptibility to age hardening. The maximum hardness for such alloys is obtained by heat treating at about 630°C. followed by artificially aging at about 265°C. for 8 hr.

The compound NiAl_3 , occurring in the binary alloys, appears under the microscope as a light gray constituent with a slightly purple tinge in the unetched condition. Keller and Wilcox,⁵ investigating the etching characteristics of constituents of aluminum alloys, found that the NiAl_3 constituent is colored brown to black in an aqueous solution of 0.5% HF . They observed that about the same coloration is obtained using an etching reagent of 10% NaOH at 70°C., or one containing 0.5% HF , 1.5% HCl and 2.5% HNO_3 . A 25% HNO_3 solution at 70°C. does not color or attack the constituent.

Constitution of Aluminum-Silicon Alloys

By E. H. Dix, Jr.,* and A. C. Heath, Jr.†

Introduction—Silicon, inevitably present in even the purest grades of aluminum, was at one time believed detrimental to the properties. Extended studies of the binary aluminum-silicon alloys disclosed the value of the element, so alloys containing up to about 13% silicon are now widely used; especially as casting alloys.

Fig. 1—Aluminum-Silicon Constitution Diagram (aluminum end). Location of eutectic by Edwards, and the liquidus curves by Gwyer and Phillips.

Fig. 2—Aluminum-Silicon Constitution Diagram (aluminum end), by Dix and Heath.

Studies of the binary aluminum-silicon system have been generally somewhat confused by the presence of iron, which produces a highly complex system, but by the use of very pure material these effects can be minimized.

Constitution Diagram—The results of early work on the system are in fairly good agreement and show it to be a simple eutectiferous system without compounds. Probably the most satisfactory determinations of the eutectic temperature (577°C) and composition (11.6% Si) are those of Edwards¹ and Gwyer and Phillips.² Alloys containing as high as 14% silicon may be caused to solidify without the separation of visible particles of primary silicon by either rapid cooling³ or the presence of "modifiers"⁴ such as sodium. This undercooling or modification produces some changes in the alloy structure which are accompanied by marked changes in physical properties. In addition, it lowers the apparent eutectic temperature from 577 to as low as 564°C.

A diagram of the aluminum end of the system is shown in Fig. 1. Dix and Heath,⁵ using thermal and microscopic methods on samples made from high purity aluminum and silicon, have more recently investigated the aluminum end of the system. Their diagram for this area is given in Fig. 2.

The identification of silicon particles under the microscope is comparatively simple as long as they are of fair size, since they can be recognized by their purple or slate color in the unetched condition. When polished with magnesia using the proper pressure they will appear flat in the matrix, but if too light pressure is used they will stand in relief and may become faded or discolored so that identification by color is not reliable. The particles are remarkably resistant to most etching reagents so the general effect of etching will be to remove surface flow and outline the constituent. A light etch with a ½% aqueous solution of hydrofluoric acid will produce this particle definition, but may somewhat discolor the constituent.

The solid solubility determinations by Dix and Heath on very pure alloys, are

Constitution of Aluminum-Titanium Alloys

By W. L. Fink* and K. R. Van Horn†

Introduction—Titanium commonly occurs in small quantities in many of the aluminum ores, and traces of titanium oxide not removed during the purification of the ore are reduced with the alumina. In this manner traces of titanium are sometimes unavoidably present in aluminum pig. Larger percentages of titanium are sometimes introduced into aluminum alloys, but it is not usually added as a major alloying element.

Constitution Diagram—The little attention which the aluminum-titanium constitution diagram has received has been restricted to the aluminum end of the system. E. van Erckelens,¹ Manchot and Leber,² and Fink, Van Horn and Budge³ have published constitution diagrams; while Wohler,⁴ Manchot and Richter,⁵ and Weiss and Kaiser⁶ described the compound existing in aluminum-rich alloys.

The liquidus, which represents the solubility curve of the aluminum-titanium constituent, $TiAl_3$, in molten aluminum, has a steep slope^{1, 2, 3} and attains a temperature of about $1350^{\circ}C.$ at 37.2% titanium ($TiAl_3$). The liquidus values of E. van Erckelens and Manchot and Leber are in agreement at the higher titanium contents, but vary appreciably at the extreme aluminum (commercial) end. Fink, Van Horn and Budge observed that the primary thermal effects in specimens of low titanium content were weak and susceptible to decided under-cooling. Therefore, these investigators determined the liquidus by a different procedure—analysis of the supernatant melt in equilibrium with precipitated $TiAl_3$. The data thus obtained are incorporated in the accompanying diagram (Fig. 1) which shows that the liquidus intersects the peritectic horizontal at $665.1^{\circ}C.$ and 0.18% titanium.

Fig. 1—Aluminum-Titanium Constitution Diagram.

Two thermal arrests have been observed³ in alloys containing over 0.03% Ti. Above 0.18% Ti these arrests occur at $665.1^{\circ}C.$ and $659.8^{\circ}C.$ respectively, while below 0.18% Ti the two points converge and meet at the melting point of pure aluminum. The lower arrest may be interpreted as the failure to obtain equilibrium during the cooling curve experiment. As chemical and X-ray analyses revealed only one compound, $TiAl_3$, some solid solubility would be necessary to explain the peritectic arrests at $665.1^{\circ}C.$ A solid solubility of approximately 0.28% titanium in aluminum at $500-650^{\circ}C.$ was determined by electrical conductivity measurement and microscopic observations. It is not definitely known whether the solubility is constant over this range or whether the rate of diffusion is so slow that equilibrium is not realized. The horizontal line at $665.1^{\circ}C.$ therefore represents the peritectic reaction $TiAl_3 + \text{liquid} = \text{aluminum solid solution}$.

Microscopic examination of binary aluminum-titanium alloys reveals the titanium phase in the form of large needles which are cross sections of plates. The constituent appears to be blue-gray in an unetched polished section. Early chemical methods gave $TiAl$, $TiAl_2$, and Ti_2Al_3 as the formula of the Al-Ti compound. Recent determinations have definitely established the formula $TiAl_3$, the crystal structure of which has been analyzed⁷ and found to be tetragonal.

Constitution of Aluminum-Magnesium Silicide Alloys

By E. H. Dix, Jr.,* F. Keller,* R. W. Graham†

General—The addition of magnesium and silicon to aluminum results in a type of strong alloy which is of considerable commercial importance. The alloys are readily workable in the annealed form and may be strengthened and hardened by a solution heat treatment. The maximum strength and hardness are obtained by a precipitation heat treatment following the solution heat treatment. The susceptibility of these alloys to heat treatment is attributed to the presence of the magnesium and silicon in the form of the compound Mg_2Si .

An extensive investigation of the constitution of aluminum alloys containing various amounts of magnesium and silicon was made by Hanson and Gayler.¹ Part of their investigation consisted of determining the solid solubility of the compound Mg_2Si in aluminum.

Constitution Diagram—In the system of aluminum, magnesium and silicon all alloys lying on the base line running from the aluminum corner of a triangle representing the ternary alloys to the point representing the compound Mg_2Si form a simple eutectiferous series. Mg_2Si forms a eutectic with aluminum at about 13% of the compound. The eutectic temperature has been found to be 595°C.

It has been generally assumed that the precipitate formed at low temperatures from the solid solution of magnesium and silicon is Mg_2Si . However, Mehl, Barrett,

and Rhines² were unsuccessful in their attempt to find evidence of the Mg_2Si lattice in their X-ray studies to identify the precipitate. Their results indicated that the compound $AlMg_2$, $(\beta Al-Mg)^3$ was present while the presence of Mg_2Si and silicon was less certain.

When a properly polished specimen is examined the compound Mg_2Si appears pale blue in color, but it readily tarnishes to a deep iridescent blue. The compound is readily attacked by water in the polishing operation which makes the preparation of samples somewhat difficult.

Etching is not desirable for identification of the constituent since all of the etching reagents commonly employed for aluminum alloys attack the compound Mg_2Si and remove its characteristic deep blue

color. However, a 0.5% solution of hydrofluoric acid in water is generally used for removing surface flow and for revealing fine particles and grain size.

The constitution of the aluminum-magnesium silicide alloys containing up to 19% of the compound Mg_2Si is shown in Fig. 1. This diagram is taken from the work of Hanson and Gayler and has been modified to include the more recently determined solubility limits.⁴ The solubility limits for Mg_2Si for various temperatures are also given in the following tabulation:

Temperature Solubility Relations

Temp., °C.	595*	500	400	300	200
Saturation limit (% Mg_2Si).....	1.85	1.05	0.53	0.30	0.27

*Eutectic temperature.

These solubility relations hold true only when the magnesium and silicon are present in the proper proportions to form the compound Mg_2Si . An excess of magnesium over that required to form the compound reduces the solubility in proportion to the amount of excess magnesium present. An excess of silicon does not affect the solubility of Mg_2Si in aluminum.

Constitution of Aluminum-Magnesium-Zinc Alloys

By W. L. Fink* and L. A. Willey*

The ternary system, aluminum-magnesium-zinc, is of particular interest because useful alloys are found in all three corners of the diagram.

The three binary diagrams are shown in Fig. 1, 2, and 3. The doubtful and extrapolated portions of the binary diagrams are shown with dotted lines. The

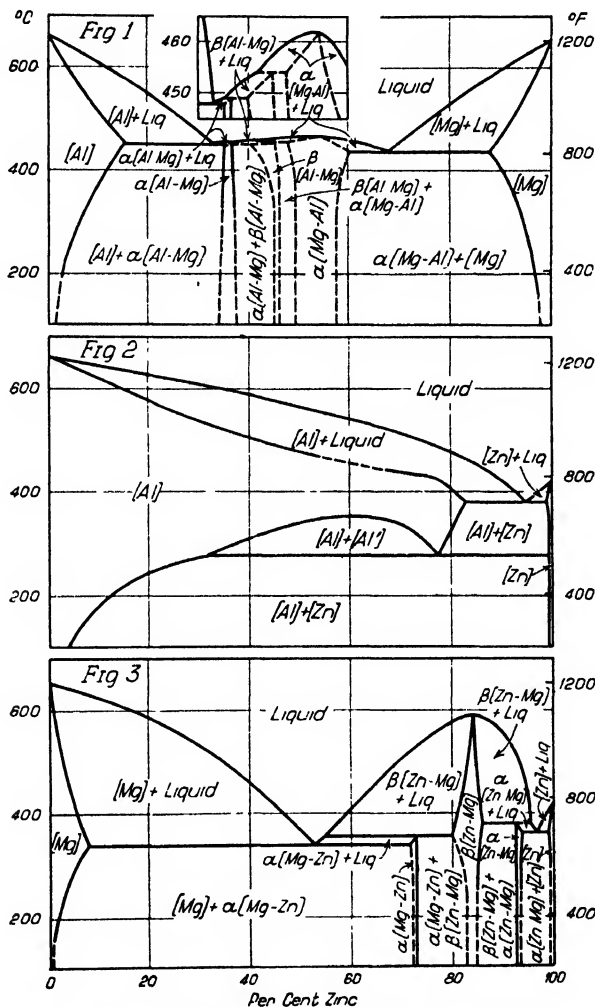

Fig. 1—Aluminum-magnesium constitution diagram.

Fig. 2—Aluminum-zinc constitution diagram.

Fig. 3—Magnesium-zinc constitution diagram.

solid lines of the diagrams were taken from various investigations which are in substantial agreement. In the binary systems as well as in the ternary system, the phases have been designated by a modification¹ of the method proposed by Dix and Keith.² A phase is designated by placing in parentheses the chemical symbols of the elements essential to the formation of that phase. The symbols

*Aluminum Research Laboratories, New Kensington, Pa.

in the parentheses are separated by dashes in order to clearly distinguish them from a chemical formula. Elements that are not necessary to the formation of the phase in question, but which may be present in solid solution, are not indicated in the designation. The symbols are placed in the order of the atomic percentage

Fig. 4—Liquidus surface, aluminum-magnesium-zinc constitution diagram (Köster, Wolf and Dullenkopf).

Fig. 5—Solidus surface, aluminum-magnesium-zinc constitution diagram (Köster, Wolf, Dullenkopf, Fink and Willey).

of the elements. If two or more phases would have the same designation according to these rules, they are distinguished by prefixing Greek letters. A list of all the phases found in the aluminum-magnesium-zinc system is given below, together with other symbols which have been used in the literature to designate these phases:

(Al) = Al, Aluminum solid solution, α , β , γ
 $\alpha(\text{Al-Mg})$ = Al_2Mg , Al_3Mg_2 , β
 $\beta(\text{Al-Mg})$ = AlMg , γ
 $\alpha(\text{Mg-Al})$ = Mg_2Al , Mg_3Al_2 , γ , δ
 (Mg) = Mg , Magnesium solid solution, α , δ , ξ
 $\alpha(\text{Mg-Zn})$ = MgZn , ζ
 $\beta(\text{Zn-Mg})$ = Zn_2Mg , η , γ
 $\alpha(\text{Zn-Mg})$ = Zn_5Mg , δ , β
 (Zn) = Zn , Zinc solid solution, α
 (Mg-Zn-Al) = T , $\text{Mg}_2\text{Zn}_3\text{Al}$, $\text{Mg}_5\text{Zn}_{10}\text{Al}_3$

Physical Constants of Aluminum

By Junius D. Edwards*

Introduction—Aluminum having a purity as high as 99.99% has only been available since the development of the Hoopes process of electrolytically refining aluminum. Previously the physical constants of aluminum were of necessity determined with metal of lower commercial purity. However, there are now available data on most of the properties of the very pure electrolytically refined aluminum. In the discussion an effort will be made to indicate the effect on the property in question of the impurities (iron, silicon, and copper) ordinarily present in commercial aluminum.

Atomic Weight—The element aluminum has the atomic number 13. Its atomic weight is 26.97 according to the present accepted value. No isotopes of aluminum are known.

Crystal Form—Aluminum, like most of the ductile metals, crystallizes in the face-centered cubic lattice. The unit edge of the lattice cube is 4.0413×10^{-8} cm. as determined on high purity aluminum.^{1, 2}

Fig. 1—Reflectivity of aluminum for radiation of various wave lengths.

Density—Aluminum (99.971% purity) has a density of 2.6989 g. per cc. at 20°C. when in the cold rolled condition and 2.6996 g. per cc. after annealing. As with most of the metals, the density is slightly decreased by cold working and increased by subsequent annealing.³ The addition to aluminum of heavy metals, such as iron, copper, and zinc, increases the density. Silicon

(density = 2.4) in amounts up to about 0.3% slightly increases the density of aluminum and thereafter decreases it.

Typical values for the density of aluminum for the temperature range of 20–1100°C. are given in Table I. The values for density are numerically equal to the specific gravity of the metal when referred to the weight of water at 4°C. The values for density (g. per cm.³) may be converted into the weight in lb. per cu.ft. by multiplying by the factor 62.428. Aluminum at 70°F. weighs approximately 168.6 lb. per cu.ft. (2.70×62.428). Data for aluminum of three different grades are given in the table.⁴ In passing from the liquid to the solid state at the freezing point, there is a contraction in volume amounting to 6.6%.

Table I

Density of Aluminum

According to J. D. Edwards

Temp.	Condition of Metal	Density—g. per cc.		
		99.75% Aluminum	99.4% Aluminum	98.25% Aluminum
Centigrade Temperature Scale				
20	Solid	2.703	2.706	2.727
100	Solid	(2.69)
200	Solid	(2.67)
400	Solid	(2.62)
658.7	Solid	(2.55)
658.7	Liquid	2.382	2.384	2.405
700	Liquid	2.371	2.373	2.394
800	Liquid	2.343	2.345	2.366
900	Liquid	2.316	2.318	2.339
1,000	Liquid	2.289	2.291	2.311
1,100	Liquid	2.262	2.264	2.285

Note—Values enclosed in parentheses are calculated from expansion formula.

(Continued)

*Asst. Director of Research, Aluminum Research Laboratories, New Kensington, Pa.

Temp.	Condition of Metal	Density—g. per cc.		
		99.75% Aluminum	99.4% Aluminum	98.25% Aluminum
Fahrenheit Temperature Scale				
68	Solid	2.703	2.706	2.727
1,217.7	Solid	(2.55)
1,217.7	Liquid	2.382	2.384	2.405
1,300	Liquid	2.369	2.371	2.393
1,400	Liquid	2.354*	2.356	2.377

1,600	Liquid	2.324	2.326	2.347
1,700	Liquid	2.309	2.311	2.332
1,800	Liquid	2.294	2.296	2.316
1,900	Liquid	2.278	2.280	2.301
2,000	Liquid	2.263	2.265	2.286

Note—Values enclosed in parentheses are calculated from expansion formula.

Note—Values enclosed in parentheses are calculated from expansion formula.

Compressibility—The compressibility or percentage change in volume with unit change in pressure of 1 megabar (0.987 atmospheres; 14,504 psi.) of electrolytically refined aluminum is approximately 1.40×10^{-6} at room temperature; the compressibility increases somewhat with rising temperature and decreases with metal of lower purity.

Thermal Expansivity—According to measurements of the Aluminum Research Laboratories,²⁸ the thermal expansivity of wrought aluminum (99.996% purity) is given by the following equation, for the temperature range of 20–500°C., L_0 is the original length and L_t the length at temperature t .

$$L = L_0 [1 + (23.22t + 0.00467t^2 + 0.0000078t^3) 10^{-6}]$$

The expansion coefficients for aluminum of different purities and for a variety of temperature ranges are given in Table II.

According to Henning,⁶ the expansion coefficient ($\alpha \times 10^{-6}$) of aluminum is 18.2 at –100°C. and 11.55 at –200°C. The following equation covers the range from 0 to –200°C.:

$$L_t = L_0 [1 + (22.65t + 0.01675t^2 - 0.00003667t^3) 10^{-6}]$$

Freezing Point—The Bureau of Standards issues a standard sample of very pure aluminum for melting point determinations, to which they assign a melting point of 660.2°C. Commercial metal having a purity of about 99.2% has a freezing point of about 657°C. (1214.6°F.).

Table II
Average Expansion Coefficients of Aluminum

Temp. Range, °C.	Average Coefficients of Expansion per °C.			
	Wrought Aluminum ²⁸ 99.996%	Cast Aluminum ⁵ 99.95%	Cast Aluminum ⁵ 99.74%	Rolled Aluminum ⁵ 99.15%
	$\times 10^{-6}$	$\times 10^{-6}$	$\times 10^{-6}$	$\times 10^{-6}$
20–100	23.86	23.8	23.8	24.0
20–200	24.58	24.7	...	25.9
20–300	25.45	25.7	25.6	26.7
20–400	26.49	26.7	...	27.2
20–500	27.68	27.7	...	27.9
20–600		28.7	29.4	28.6
100–200		25.5		
200–300		27.5		
300–400		29.5		
400–500		31.5		
500–600		33.5		
300–600		31.5		

Specific Heat—The specific heat of aluminum as well as the heat content are given in Table III. Recent work of Seekamp²⁹ is in close agreement with the data of Table III.

Latent Heat of Fusion—The latent heat of fusion of aluminum is approximately 93 cal. per g. (167.4 B.t.u. per lb.), which is an average of the closely agreeing results of Wurst, Meuthen and Duerrert¹ and of Awbery and Griffiths.³

Boiling Point—The boiling point of aluminum is not known with great certainty but according to Greenwood⁹ it is 1800°C. (3272°F.). The metal is relatively non-volatile at ordinary melting and casting temperatures. Its vapor pressure is estimated by Johnston¹⁰ to be about 0.001 mm. of mercury at 730°C., 0.01 mm. at 830°C., and 0.1 mm. at 950°C. According to Johnston's estimate, the heat of vaporization is approximately 52,600 g. cal. per mol (27.0 g.) or 3506 B.t.u. per lb.

Table III
Heat Content and Specific Heat of Aluminum
Arranged by Shadgen⁷ from Data of Wuest, Meuthen, and Duerr

°C.	Temp. °F.	Heat Content		Specific Heat	
		B.t.u. per lb.	Calories per kg.	Mean 0°-T°	At T°
0	32	0.2220
100	212	40.66	22.59	0.2259	0.2297
200	392	82.69	45.94	0.2297	0.2374
300	572	126.12	70.07	0.2336	0.2451
400	752	170.95	94.97	0.2374	0.2529
500	932	217.15	120.64	0.2413	0.2606
600	1,112	264.76	147.09	0.2452	0.2683
657 (Solid)	1,214.6	292.50	162.50	0.2473	0.2727
657 (Liquid)	1,214.6	461.63	256.45	0.3904	0.2502
700	1,292	481.09	267.27	0.3818	0.2523
800	1,472	526.93	292.74	0.3659	0.2571
900	1,652	573.66	318.70	0.3541	0.2619
1,000	1,832	621.26	345.14	0.3451	0.2667

Thermal Conductivity—The precise measurement of the thermal conductivity of metals is a difficult problem and it is not surprising that there is wide variation in the published data. The Bureau of Standards¹¹ reports that aluminum, 99.66% pure, has a thermal conductivity of 0.52 (cal. per sec. per sq. cm., per cm. of thickness per °C.) at an approximate temperature of 50°C. The thermal conductivity decreases with decrease in purity. Apparently it increases slightly with increase in temperature up to several hundred °C., but observers are not unanimous on this point. The average of scattered values of some 12 different investigators are as follows: 0.503 at room temperature; 0.503 at 100°C.; 0.530 at 200°C.; 0.546 at 400°C. A thermal conductivity of 0.52 in cgs. units is equivalent to 1509 B.t.u. per hr. per sq. ft. per in. of thickness per °F.

Heat of Combustion—The heat of combustion of aluminum with oxygen is high and accounts for the ready reduction of many oxides by reaction with aluminum. The average of the results of four investigations (Minet,¹² Berthelot,¹³ Richards,¹⁴ Parr and Moose¹⁵) is 383,900 cal. per mol of alumina formed ($2\text{Al} + 3\text{O} = \text{Al}_2\text{O}_3$), which is equivalent to 12,800 B.t.u. per lb. of aluminum.

Fluidity—The fluidity (reciprocal of viscosity) of aluminum according to the data of Losani¹⁶ is given in Table IV. The results are referred to the fluidity of tin at 300°C. as unity. The fluidity of aluminum is appreciably increased by the addition of small amounts of alloying elements.

Table IV
Fluidity Index of Aluminum
According to Losani

Temp., °C.	Fluidity Index— Fluidity of Pure Tin at 300°C. = 1.00	
	Aluminum Purity = 99.26%	Aluminum Purity = 98.32%
680	0.51	0.67
700	0.70	0.75
750	0.84	0.88
800	0.93	0.97
850	0.97	1.02
900	1.00	1.05
950	1.02	1.09
1,000	1.05	1.15

Optical Properties—Aluminum ranks high among metals as a reflector for ultra-violet light.¹⁷ In the visible range, reflectivity values as high as 90% have been recorded,¹⁸ while in the infra-red range the reflectivity increases to values of over 97%.¹⁹ Fig. 1, taken from an article by Edwards,¹⁹ shows the reflection factor for aluminum over a wide range of wave lengths; means of preparing aluminum reflectors are described in this article.

The emissivity of commercial aluminum foil is about 0.03 at room temperatures.²⁰

Moeller and Miething²⁰ found the emissivity of molten aluminum in contact with air to be 0.12 at 700°C. and 0.17 at 1000°C. The formation of an oxide film upon the metal had an appreciable effect upon the results and would tend to increase the observed emissivity.

Electrical Resistivity—Some of the electrical properties of annealed wire made from electrolytically refined aluminum with a purity of 99.996% are given in Table V. The resistivity is slightly increased by cold working.

Table V
Electrical Properties of High-Purity Annealed Aluminum Wire

Property	Value at 20°C.
Density	2.699 g. per cm. ³
Specific volume electrical resistivity, microhms per cm. cube.....	2.6548 × 10 ⁻⁶ ohms
Volume conductivity.....	64.94%
International annealed copper standard = 100	
Specific mass resistivity, ohms per m.g.....	0.07165 ohms
Mass conductivity.....	213.92%
International annealed copper standard = 100	
Constant mass temperature coefficient of resistivity.....	0.00429

The resistivity of liquid aluminum at its freezing point is 20 microhms per cc. according to Northrup,²¹ and 27 microhms per cc. according to Bornemann and Wagemann.²² The ratio of the resistivities of the liquid and solid at the melting point is about 1.64.

Aluminum Conductors—Commercial aluminum conductors are generally made from aluminum having a purity of about 99.5%. The American Institute of Electrical Engineers has adopted a tentative standard (No. 46) for the properties of hard drawn aluminum conductors, of which the principal parts are as follows:

1. **Resistivity**—At a temperature of 20°C. the electrical resistivity is 2.828 microhm-cm. (See Note 1.)
2. **Resistance Temperature Coefficient**—The 20°C. resistance temperature coefficient is 0.00403 per °C. (See Note 2.)
3. **Density**—At a temperature of 20°C. the density is 2.703 g. per cm.³
4. **Length Temperature Coefficient**—The 20°C. length temperature coefficient is 0.000023 per °C. (See Note 3.)
5. **Change in Resistivity with Change in Temperature**—The change in resistivity with change in temperature is 0.0115 microhm-cm. per °C. (See Note 4.)

Explanatory Notes

1. The values given above are consistent with resistivities at 20°C. of 17.01 ohm circular mil per ft. and 0.07644 ohm g. per sq. m., and a conductivity at 20°C., as compared with the annealed copper standard at 20°C. of 60.97%.

2. The value taken for the resistance temperature coefficient is the amount by which the resistance of a conductor of standard hard drawn aluminum changes when the temperature is changed, divided by the change in temperature expressed in °C., and divided by the resistance of the same conductor when at a temperature of 20°C.

3. The value taken for the length temperature coefficient (linear expansion coefficient) is the amount by which the length of a conductor of standard hard drawn aluminum changes when the temperature is changed, divided by the change in temperature expressed in °C., and divided by the length when at a temperature of 20°C.

4. The value taken for the change in resistivity with change in temperature, as given in paragraph 5, is the sum of the resistance temperature coefficient and the length temperature coefficient, multiplied by the resistivity at 20°C., as given in paragraphs 1, 2, and 4.

Electrochemical Equivalent—The electrochemical equivalent of aluminum is the number of g. deposited per sec. by a current of 1 ampere or the g. per coulomb. It is equal to the atomic weight, 26.97, divided by the valence, 3, and the constant 96,500, or 0.09316 mg. per coulomb. In various units it is as follows:

Electrochemical Equivalent of Aluminum

Unit	Value
Mg. per coulomb.....	0.09316
Coulombs per mg.....	10.734
G. per ampere hr.....	0.3354
Lb. per 1,000 ampere hr.....	0.7395
Ampere hr. per lb.....	1352.3

Electrolytic Solution Potential—According to standard terminology, aluminum is electronegative to the elements which it replaces in solution; the aluminum going into solution in the form of positive ions leaves the metal negatively charged, hence the characterization "electronegative." There is some question as to its exact position in the electrochemical series. In fact, its relative position appears to vary with the conditions under which it is tested, for example, the solute and solvent employed. Generally aluminum is considered to be electropositive to magnesium and electronegative to such metals as manganese, zinc, cadmium, iron, nickel, and copper. Under many practical conditions and probably because of film formation, zinc is found to be electronegative to aluminum.

Kahlenberg and French²⁸ have measured the potential of high purity aluminum (99.97%) in contact with aqueous normal solutions of potassium chloride. The potential was depressed when the solution contained dissolved oxygen, but when the oxygen was displaced with nitrogen, the pure aluminum showed an initial voltage against the normal calomel electrode of 1.716. In solutions in contact with air, the aluminum showed a potential of 0.8-1.0 volts. The single potential of the aluminum is 1.716 volts minus 0.56 (the potential of the calomel electrode) or 1.16 volts. According to Latimer and Greensfelder,²⁷ the electrode potential of aluminum at 25°C. has been calculated from thermal data to be 1.69 ± 0.01 volts.

Thermoelectromotive Force—The Bureau of Standards²¹ has determined the thermal emf. of electrolytically refined aluminum (99.968% purity) against pure platinum to be +0.416 millivolts at 100°C.; 1.064 at 200°C.; 1.884 at 300°C.; 2.843 at 400°C.; 3.931 at 500°C.; 5.150 at 600°C. The emf. corresponds to the temperatures of the hot junctions with the cold junctions at 0°C.; the plus sign indicates that the aluminum was at the higher potential. A sample of 99.972% purity had an emf. of 0.415 millivolts at 100°C.

Magnetic Properties—The purest aluminum is slightly but definitely paramagnetic. Apparently traces of iron in the aluminum, combined as FeAl₃, have only slight effect upon the magnetic properties of the metal. Honda²⁹ reports a value of $+0.65 \times 10^{-6}$ for the magnetic susceptibility (k) at 18°C., of aluminum with 0.08-0.24% iron and 0.695×10^{-6} for metal with an iron content of 0.80%.

Mechanical Properties—Aluminum of high purity is characterized by exceptional ductility and softness. A sample of 99.97% purity had the following mechanical properties in the wrought annealed condition:²

Tensile strength	8,500 psi.
Elongation	60% in 2 in.
Using the standard 0.5 in. dia. A.S.T.M. specimen	
Reduction in area.....	95%
Brinell number, with 50 kg. pressure and 0.125 in. ball.....	16

Aluminum of substantially lower purity, say 99.4% (annealed), will have about the following properties, which are interesting as a matter of comparison:

Tensile strength	13,000 psi.
Elongation	22
Reduction in area.....	80%
Brinell hardness	45 in 2 in.

Properties of Commercially Pure Wrought Aluminum

By P. V. Faragher*

General—Commercially pure wrought aluminum (2S) contains small quantities of iron and silicon. It is available in practically all of the forms used in the metal industry. It possesses excellent workability and a high degree of resistance to corrosion and is generally used in applications requiring these properties rather than strength.

Composition—Specifications for commercially pure aluminum require a minimum of 99% aluminum.

Specific Gravity—The specific gravity of the metal is 2.71. One cu.in. weighs 0.098 lb.

Temper Designations—Temper of wrought aluminum is designated by a symbol or symbols following the alloy designation.

The suffix "O" designates annealed material while "H" indicates the full hard temper attained by cold working a definite amount after annealing. Cold worked tempers intermediate between the annealed and full hard are indicated by a fraction preceding the symbol "H," corresponding to the properties intermediate between annealed and hard rolled.

Mechanical Properties—Typical mechanical properties of commercially pure wrought aluminum in the various tempers are given in Table I.

Table I
Mechanical Properties¹ of Wrought Aluminum (2S)

Temper Designation (See Text)	Tensile Strength Psi.	Yield Strength ² Psi.	Elongation ³ , % in 2 in.	Brinell Hardness ⁴ No.	Shearing Strength ⁵ Psi.
O (Annealed)	13,000	5,000	35	23	9,500
1/4H	15,000	13,000	12	28	10,000
1/2H	17,000	14,000	9	32	11,000
3/4H	20,000	17,000	6	38	12,000
H (Hard)	24,000	21,000	5	44	13,000

¹Young's modulus of elasticity is approximately 10,300,000 psi. Rotating beam endurance limit (R. R. Moore type machine, 500,000,000 cycles) for 2S-O is 5,000 psi. and for H is 8,500 psi.

²Stress which produces a permanent set of 0.2% of the initial gage length. Yield strengths in tension and compression are substantially the same.

³Typical values for sheet 1/4-1/2 in. in thickness. Heavier sections, from which standard, round specimens are taken, will have higher elongations.

⁴10 mm. ball, 500 kg. load.

⁵Single shear strength values obtained from double shear tests.

Resistance to Corrosion—Commercially pure aluminum is highly resistant to the action of the atmosphere and a variety of chemicals. It is attacked by strong alkalis and to some extent by weak alkaline solutions. In the latter case the action may be inhibited by small additions of such compounds as sodium silicate or the chromates of sodium or potassium.

Workability—In its wrought forms the metal may be formed readily on the equipment commonly used for bending, spinning, drawing, and stamping metals. It is most workable in the annealed temper, although in the half hard temper it can be bent flat on itself. Less severe forming can be done in the harder tempers.

Welding Characteristics—Welding is easily accomplished with the oxyhydrogen or oxy-acetylene flame, the metal arc (except for thin sheets), and electric resistance processes. Some practice and experience is necessary for consistently reliable results, but the technique is not difficult to master. A welding rod of the same composition is used for work on the commercially pure metal and a suitable flux is necessary. Spot, butt, and seam welding are applicable but require more powerful equipment than is used on steel.

Annealing Treatment—The fully annealed properties are obtained by heating to 650°F. followed by air cooling.

*Aluminum Co. of America, Pittsburgh.

Applications and Forms Produced—The uses of commercially pure aluminum vary widely, but are typified in cooking utensils and chemical equipment. The metal is especially useful where a high degree of formability is necessary.

The metal is produced in the usual wrought forms such as sheet, plate, tubing, bar, rod, wire, rivets, molding, and other shapes.

Bars, rods, shapes, and plates over $\frac{1}{4}$ in. thick are normally hot rolled and their strength is somewhat above that of annealed material; no attempt is made to produce definite tempers. Cold finished bars and rods are harder and stronger. Plates are produced in tempers up to half hard, but when such properties are wanted it is usually more economical to use the as-rolled temper of a stronger alloy.

Properties of Aluminum-Copper Alloys

(General Article)

By E. H. Dix, Jr.,* and J. J. Bowman*

General—The aluminum-copper alloys as a class are probably the oldest and most widely used of any commercial aluminum alloys. The commercial alloys of aluminum and copper are, in general, not strictly binary alloys, but are modified by small amounts of other elements. The aluminum-copper alloy containing about 4% copper forms the base for some of the most important heat treatable, high strength aluminum alloys, both cast and wrought.

Casting Alloys

Casting Characteristics—The casting and general foundry characteristics of the commercial aluminum-copper alloys are very good. The addition of copper decreases, progressively, shrinkage difficulties and hot shortness, so that with 12% copper, leak-proof castings are readily produced. The 8% copper alloy is a good, general purpose alloy, but may give some trouble in casting if the iron and silicon contents are not properly controlled.

Mechanical Properties—The results of a limited investigation of sand cast, aluminum-copper alloys are shown by the curves of Fig. 1. As these curves show, the strength increases and the elongation decreases in direct proportion to the copper content. The most rapid changes in the properties are produced by copper additions of about 5% or less. The alloys containing more than about 10% copper are comparatively brittle, but are still of reasonable commercial value.

Fig. 1

Fig. 2

Fig. 1—Tensile properties of aluminum-copper alloys in the form of $\frac{1}{2}$ in. dia. test bars cast in green sand.²

Fig. 2—Properties of high purity aluminum-copper alloys after hot rolling. Heating 1 hr., at 540°C., quenching in cold water, and aging as indicated (R.T. = room temperature).

increases with an increase in copper content, the upper limit for practical production of such alloys is probably 5-6% of copper. Such high purity alloys containing up to 5% copper can be hot rolled with relative ease and in the annealed condition have a greater capacity for cold work than the aluminum-copper alloys containing other added elements.

Mechanical Properties—Several investigations of the wrought high purity, aluminum-copper alloys have been made to determine the relations between copper content and mechanical properties. These studies indicate that, within reasonable

The mechanical properties of these binary alloys are subject to marked improvement by suitable heat treatments.¹ The commercial alloy most commonly used in the heat treated condition is that containing about 4% copper, because this composition will produce a suitable combination of strength and ductility in sand castings. The alloys of higher copper content, however, are frequently heat treated to increase hardness and toughness.

Wrought Alloys

Rolling Characteristics—Binary alloys of high purity containing up to 10% copper have been successfully rolled on a small scale, but since the difficulty of working in-

*Aluminum Research Laboratories, New Kensington, Pa.

²The Aluminum Industry, v. II, p. 144. Fig. 2 from p. 147.

limits, the mechanical properties of annealed or hard rolled sheets are not greatly affected by variations in copper content from about 2.5-5% or somewhat higher.

The curves of Fig. 2 are a portion of the results of these investigations and illustrate clearly the effect of copper content on the mechanical properties of heat treated sheet. They illustrate the very definite increase in strength and hardness accompanying increased copper content and the unmistakable hardening (or precipitation) effect of room temperature aging. The further effect of aging at an elevated temperature is marked. The elongation in the "as-quenched" condition is quite high and is not greatly affected by variations in copper content. Similarly, there is not a great variation in elongation attributable to copper content in alloys aged 11 days at a room temperature. The definite maximum in this curve at from 4-4.5% copper should be noted.

Other Characteristics

Density—Both the solid and liquid densities of the aluminum-copper alloys, as would be expected, increase with the copper content. At 20°C. the density of the sand cast alloy containing 4% copper is about 2.77, while that of the 8% copper alloy is about 2.83. At 700°C. the values for these alloys become, respectively, about 2.44 and 2.53.

Thermal and Electrical Conductivity—In general, the thermal and electrical conductivities of aluminum are reduced by alloying additions, although the latter property is not as greatly affected in aluminum alloys as in the alloys of some of the other metals. Additions of copper to aluminum, in accordance with the general rule, decrease progressively both the thermal and electrical conductivities so that, with 8% copper present, the former becomes about 0.34 cgs. units and the latter is about 35% of the copper standard.

Thermal Expansion—The coefficients of thermal expansion of aluminum-copper alloys decrease continuously with increasing copper content from about 0.000024 per °C. (20-100°C.) for pure aluminum to about 0.000020 for the 33% copper alloy. The rate of decrease is greatest from 0 to about 8% copper.¹

Endurance Limit—The rotating beam endurance limit (500 million cycles) of the aluminum-copper alloys increases with increase in copper content and, for a given alloy, is improved by solution heat treatment.

Resistance to Corrosion—The addition of copper, in excess of the limit of solid solubility, tends to lower the high resistance to corrosion of pure aluminum, so that the resistance to corrosion of the aluminum-copper alloys is generally inferior to that of the aluminum-silicon, aluminum-manganese, and aluminum-magnesium alloys, but is satisfactory for most applications especially in relatively thick sections, as in castings. Thin sheets of the aluminum-copper alloys generally require protective measures to resist severely corrosive condition. Solution heat treatment definitely improves the resistance to corrosion, but subsequent precipitation heat treatments cause some reduction in this property, although the resulting product is definitely superior to the alloy in the unheat-treated condition.

Properties of Aluminum-Copper (8%) Casting Alloys

By H. J. Rowe*

The aluminum casting industry in America has developed around alloys in which copper was the principal hardening constituent. Most important of this group of alloys still in general use are those in which approximately 8% copper is used as the chief alloying element. Later improvements in the simple binary alloy have led to the addition of controlled amounts of silicon, iron, and zinc, resulting in alloys with better casting characteristics and machinability. The chemical compositions and specifications for the aluminum-copper casting alloys in most general use are given in Table I, and the mechanical and physical properties in Table II.

Table I
Chemical Composition of 8% Copper Casting Alloys (Approx.)

Alloy	Copper %	Iron %	Silicon %	Zinc %	Aluminum (Min.) %
A	8.0	90.0
B	7.0	1.2	2.0	1.5	86.5
C	8.0	1.0	1.2	89.0
D	7.0	1.2	3.0	2.0	85.5
E	7.0	2.0	85.0

General Properties and Uses—The aluminum-copper casting alloys containing 8% copper, although superseded in some fields of application by newer alloys with improved properties, still account for a large part of aluminum alloy casting production. They possess a desirable combination of general casting characteristics, good machinability, and fair mechanical properties, which warrant their use in a variety of fields.

Alloy A, the oldest of the group, is being replaced to a great extent by Alloys B, C, D and E because of their better casting characteristics and the better machinability as judged by surface appearance, offered by Alloys B and D. The composition limits for Alloys B and D are also such as to permit the use of various amounts of secondary material.

The corrosion resistance of this group of alloys, because of the high copper content, is not in general so good as that of many of the low copper alloys, such as aluminum-silicon, and aluminum-magnesium alloys.

One of the first uses for castings of the 8% copper alloys was in the automotive industry, where the mechanical properties were quite satisfactory for such parts as crankcases, oil pans, transmission housings, manifolds, and miscellaneous fittings for bodies, chassis and engine. Many parts for washing machines, vacuum cleaners, multigraphs, typewriters, and other machines, not subject to extreme stresses and impact, are produced in these alloys. It is estimated that 50% of the aluminum foundry output of castings is made in 8% copper alloys.

Properties of Heat Treated Aluminum-Copper (4%) Casting Alloys

By H. J. Rowe*

Certain of the aluminum alloys derive exceptional mechanical properties from heat treatment operations. The 4% copper alloy with controlled amounts of silicon and iron† is the most generally known of these high strength casting alloys. By varying the heat treatment of this alloy, several combinations of mechanical properties may be obtained to fit particular engineering requirements.

The properties of the 4% copper alloy with a minimum of 93% aluminum in three standard heat treated conditions are as follows:

Physical Properties of Heat Treated Copper Casting Alloy (4% Cu)

General Properties and Uses—The casting characteristics of this 4% copper alloy are not quite so good as those of the 8% copper alloys. However, with proper foundry technique, large and intricate castings can be cast and heat treated successfully. In any of the heat treated conditions the 4% copper alloy machines very readily to a smooth surface. It also exhibits good corrosion resistance, particularly in the "A" heat treated condition. The corrosion resistance in the "B" and "C" condition is slightly inferior to that of the "A."

The 4% copper alloy with heat treatment "A," a solution treatment followed only by a quench, possesses the highest ductility and impact resistance, and is to be recommended where maximum shock resisting properties combined with high strength are required. The yield strength of the solution treated alloy increases

†U. S. Patent No. 1,572,487.

substantially during the first few days at room temperature, then more slowly for a period of a few months, after which there is no further appreciable change. During this period, some increase in tensile strength and decrease in elongation also takes place. The mechanical properties given in the above table are representative of specimens tested with not less than two days or more than four days of room temperature aging.

Heat treatment "B," consisting of a solution treatment followed by a partial precipitation treatment, results in a material increase in yield strength, tensile strength, hardness, and a reduction of elongation to a point still consistent with engineering requirements. For general engineering purposes this treatment has found wide favor because of the excellent combination of mechanical properties which result.

Heat treatment "C" carries the precipitation treatment following the solution treatment to such a length as to produce the maximum hardness, yield strength, and tensile strength combination consistent with the avoidance of excessive brittleness. This treatment is desired where maximum yield strength is necessary and the castings are not subjected to excessive impact conditions.

The heat treated 4% copper alloy finds numerous applications in cast parts for aircraft engines and fuselage fittings, outboard motor parts, automotive and marine castings, Diesel engine crankcases, and railway car fittings. The choice of heat treatment will depend upon operating conditions and mechanical properties desired. For the more intricate castings, those requiring pressure tightness, and those subjected to extreme corrosive conditions, this alloy is being replaced to some extent by the more recently developed heat treated aluminum-silicon-magnesium alloys.¹

A nominal 4% copper alloy with a minimum aluminum content of 94.5%² has also found some commercial use because of the higher mechanical properties after heat treatment. This alloy is, however, very difficult to cast and cannot be used successfully for intricate castings.

The 4% copper alloy with slight variations in composition to insure the necessary casting characteristics, may also be used in the production of permanent mold castings. In the heat treated condition such permanent mold castings will exhibit considerably higher mechanical properties than those given for sand castings.

Properties of Aluminum-Magnesium Alloys

By L. W. Kempf* and F. Keller†

The binary alloys of aluminum with magnesium attracted the interest of investigators as early as the year 1900, and there have been numerous attempts to utilize for general purposes alloys containing up to 10% magnesium. Alloys containing as high as 30% magnesium have been used for special purposes.

The aluminum-magnesium alloys are lighter than aluminum, have good physical properties, excellent resistance to corrosion and are easily machined. The relatively high cost of magnesium and certain fabricating difficulties sufficed to retard their commercial exploitation. The price of magnesium has been considerably reduced and some success has been attained in overcoming some of the fabricating difficulties.

Contemporaneous efforts are being made both in this country and abroad to exploit commercially some of the aluminum-magnesium type alloys. In this country there has been some production in the form of castings of alloys containing about 4% and about 10% magnesium. Wrought alloys containing from about 1-6% magnesium as the principal alloying ingredient are also being introduced to the trade. Abroad a casting alloy containing 2-3% magnesium with additions of manganese and antimony is being produced. Wrought alloys containing 5-9% magnesium are being marketed abroad principally in the form of sheet.

Density—The densities of solid aluminum-magnesium alloys decrease continuously with magnesium content as indicated by the curve of Fig. 1.

Thermal Expansivity—The coefficient of thermal expansion of magnesium is somewhat higher than that of aluminum and the expansivity of aluminum-magnesium alloys increases with magnesium content according to Fig. 2.

Growth—The precipitation of magnesium constituent from a supersaturated aluminum solid solution is accompanied by a slight decrease in density. An alloy containing 10% magnesium in solid solution showed, upon heating to the neighborhood of 400°F. for a sufficient period of time to bring about complete stabilization, a change in density corresponding to a unit linear expansion of 0.0015.

Electrical and Thermal Conductivity—The electrical conductivity of aluminum decreases continuously with increasing magnesium content as shown by Fig. 3. Determinations on which this curve was based were made on alloys quenched from a high temperature solution treatment. Alloys so treated as to contain a minimum amount of magnesium in solid solution would ordinarily have appreciably higher electrical conductivities than are indicated by this curve.

A knowledge of the general relationship between electrical and thermal conductivity of aluminum alloys permits the estimation of thermal conductivity from electrical conductivity as indicated in Fig. 3.

Casting Characteristics—Alloys containing up to about 5% magnesium may be cast in ordinary green sand molds. When so cast, especially in heavy sections, alloys with magnesium concentrations higher than this develop a dark, porous outer ring. This effect is commonly referred to as burning and appears to consist largely of intergranular cavities, presumably caused by shrinkage and reaction of the aluminum-magnesium intermetallic compound with moisture or the atmosphere. The alloys tend to dross badly when molten, which tendency increases with magnesium content. These difficulties have been overcome successfully in a commercial way by the development of foundry technique. Inherently the aluminum-magnesium alloys are not especially difficult to cast, being quite fluid and not especially hot short, very little difficulty having been encountered from cracking in the relatively large castings. Pressure tight castings are not as easily obtained with the aluminum-magnesium as with the aluminum-silicon alloys.

Tensile Properties and Hardness of Sand Castings—The variation in mechanical properties of sand cast aluminum-magnesium alloys with magnesium content is shown in Fig. 4.

The variation in solid solubility of magnesium in aluminum from about 15% at the eutectic temperature of 451°C. to less than 4% at room temperature renders

*Aluminum Research Laboratories, Aluminum Co. of America, Cleveland.

†Aluminum Research Laboratories, Aluminum Co. of America, New Kensington, Pa.

some of the alloys susceptible to improvement in properties by heat treatment. The curves of Fig. 5 show the variation in properties of heat treated sand castings with magnesium content. These properties were attained by subjecting the castings to a solution heat treatment near the eutectic temperature for a sufficient period of time to bring about substantially complete solution of the magnesium constituent or saturation of the aluminum solid solution. The castings were quenched in water from the solution heat treatment. A comparison of the curves of Fig. 4 with those of Fig. 5 indicates that heat treatment brings about a profound change in the properties of alloys containing more than 6% magnesium. These properties were determined on $\frac{1}{4}$ in. dia. test bars cast in green sand of alloys whose impurity contents were carefully controlled, the iron and silicon contents being not more than 0.25% and copper rarely higher than 0.15%.

Working Characteristics—Alloys containing up to 2 or 3% magnesium can be reduced from cast ingots by forging or rolling with little difficulty. With increasing magnesium contents above about 3%, breaking down cast ingots becomes increasingly difficult. Even at the optimum hot working temperature, the alloys appear quite hard and are subject to considerable breakage, edge cracking, and surface checking. These conditions have precluded the commercial development and application of wrought alloys containing more than about 6% magnesium in spite of the fact that sheet and other wrought products containing up to 10% magnesium may be produced in limited sizes and at an excessive cost. The alloys may be extruded with magnesium concentrations as high as 25%. Extrusion rates decrease rapidly with increase in magnesium content.

Properties of Wrought Alloys—Fig. 6 shows the change in tensile properties and hardness of aluminum-magnesium alloys with variation in the magnesium content. Up to about 10% magnesium the data from which Fig. 6 was derived were obtained from forged bars. Above 10% magnesium the material from which the test bars were taken was produced by extrusion. The test specimens were heated near the eutectic temperature for a sufficient period of time to bring about substantially complete solution of the intermetallic constituent or saturation of the aluminum solid solution and then quenched in water. The alloys were of high purity, containing not more than about 0.1% each of iron, silicon, and copper. It will be noted that tensile strength increases to a maximum at about 15% magnesium which approximates the maximum solubility of magnesium in solid aluminum. As the magnesium content increases above this concentration, the tensile strength falls quite rapidly. Brinell hardness and yield strength increase continuously with magnesium content. A relatively constant elongation of about 32% from 2-12% magnesium is noteworthy.

Fig. 7 shows the mechanical properties obtained on a series of specimens of sheet alloys containing from 1-10% magnesium. Fig. 8 shows the properties of the same series of alloys after a reduction in thickness of 75% by cold working.

Impact Resistance—The impact resistance of aluminum as measured by notched bar Charpy or Izod tests increases with magnesium content up to at least 6% magnesium, the Izod impact resistance of the 6% alloy being about 38 ft-lb. as compared with about 21 ft-lb. for annealed commercially pure aluminum and about 16 ft-lb. for commercial duralumin. The heat treated sand cast alloy containing 10% magnesium has a Charpy impact resistance of about 4.5 ft-lb. as compared with 2.8 ft-lb. for the commercial heat treated 4% copper casting alloy.

Fatigue Resistance—The endurance limit based on 500,000,000 reversals of stress of wrought aluminum is increased with magnesium content from about 5,000 psi. at 0 magnesium to about 20,000 psi. at 6% magnesium. With higher magnesium concentrations the rate of increase is much slower, the 10% magnesium alloy having an endurance limit of about 21,000 psi. The effect of increasing concentrations of magnesium on the endurance limit of aluminum is shown in Fig. 9. The aluminum-magnesium alloys have a higher ratio of endurance limit to tensile strength than the aluminum-silicon, aluminum-copper, or aluminum-zinc alloys.

Properties at Elevated Temperatures—As indicated in Fig. 10 and 11 for sand castings of a 4 and a 10% magnesium alloy respectively, tensile properties of these alloys at elevated temperatures are relatively higher than those of alloys of the aluminum-silicon or aluminum-zinc systems but generally not as high as the corresponding aluminum-copper alloys. Fig. 11—Tensile properties of 10% magnesium alloy sand cast test bars at elevated temperatures.

were determined on test bars cast to size in green sand and heated at the temperature of testing for such periods of time as required to bring about complete stabilization.

Resistance to Corrosion—The resistance of the cast aluminum-magnesium alloys to atmospheric and salt spray corrosion is excellent, being of a different order of magnitude than that of casting alloys of the aluminum-silicon, aluminum-copper, or aluminum-zinc systems. The aluminum-magnesium alloys generally preserve a better appearance and suffer less loss in mechanical properties than the more common casting alloys. As in most aluminum alloys, the presence of impurities has a marked adverse effect on resistance to corrosion.

The wrought alloys also in the compositions being produced commercially in this country have excellent resistance to corrosion.

The aluminum-magnesium alloys are also the most resistant to alkaline corrosion of any of the aluminum alloys. Resistance to this type of corrosion increases with magnesium content.

Properties of Heat Treated Aluminum-Magnesium (10%) Casting Alloy

By L. W. Kempf* and H. J. Rowe†

The binary aluminum alloy containing 10% magnesium has the lowest specific gravity and is capable of developing the highest tensile strength of any of the aluminum casting alloys in commercial use at present. The mechanical properties after a high temperature solution treatment and some of the physical properties of this alloy are given in the following table:

Physical Properties of Heat Treated 10% Magnesium Casting Alloy

Ultimate tensile strength, psi. (Min. to average) ¹	42,000-45,000
Yield strength, psi. (average) ²	25,000
Elongation, % in 2 in. (min. to average).....	12.0-14.0
Brinell hardness, 10 mm. ball—500 kg. load.....	70-85

Society of Automotive Engineers.....	SAE 324

General Properties and Uses—The casting characteristics of the 10% magnesium alloy are slightly inferior to those of the 4% copper alloys. The high magnesium concentration necessitates a special foundry technique to avoid oxidation of the surface of metal with the consequent darkening of the casting and loss in mechanical properties. This alloy is not generally recommended for castings which must be leak proof.

In addition to the superior mechanical properties, the excellent corrosion resistance and low specific gravity of the 10% magnesium alloy are worthy of note. The alloy machines with less tool wear but with longer chips to as smooth a finish as the 8% copper casting alloy.

The principal uses of the heat treated 10% magnesium alloy to date have been in railroad car construction. Such castings as truck frames, electric motor housings, car body fittings, bolsters, and draft gear parts have been satisfactorily produced. In addition, this alloy is recommended for clamshell and drag line bucket fittings, miscellaneous automotive castings, and all general castings requiring maximum strength and impact resistance.

Properties of Aluminum-Magnesium (4%) Casting Alloy

By L. W. Kempf* and H. J. Rowet†

This alloy is characterized by its low specific gravity, excellent mechanical properties, machinability and corrosion resistance, and ability to take and hold a high white polish. The casting characteristics are not so good as those of the aluminum-silicon alloys, especially in intricate castings. The mechanical and physical properties are listed in the following table:

Physical Properties of 4% Magnesium Casting Alloy

Ultimate tensile strength, psi. (min. to average) ¹	22,000-25,000

American Society for Testing Materials.....	B26-37T Alloy L	B58-37T Alloy L

General Properties and Uses—As mentioned above, the casting characteristics of the 4% magnesium alloy are somewhat inferior to those of the aluminum-silicon alloys. Although it handles satisfactorily in castings of uniform section, it is somewhat difficult to cast in heavy intricate shapes, especially if pressure tightness is required. These limitations can in most cases be overcome, however, through modified foundry practice.

The excellent combination of mechanical and physical properties exhibited by the 4% magnesium alloy, particularly corrosion and tarnish resistance, makes this alloy very desirable for use in sanitary dairy equipment, cooking utensils, pipe fittings, carburetor cases and small ornamental castings requiring a high white polish. The alloy machines to a smooth surface with a relatively low rate of tool wear which adds materially to its utility for small mechanical fittings and housings.

For use with permanent molds, the composition of this alloy is modified slightly to give the desired casting characteristics.

Properties of Wrought Aluminum-Manganese Alloy

By P. V. Faragher*

General—Wrought aluminum-manganese alloy (3S) is similar to commercially pure aluminum, but it has higher hardness and strength with concurrent reduction in workability. It is available in the annealed, intermediate, and full hard tempers and in the usual forms and shapes.

Composition—The following comprises a commercial specification. Also the alloy contains small amounts of iron and silicon as found in commercially pure aluminum.

Manganese	1.0- 1.5%
Copper (max.)	0.2%
Aluminum (min.)	97.0%

Specific Gravity—The specific gravity of this alloy is 2.73. One cu.in. weighs 0.099 lb.

Temper Designations—The temper of wrought aluminum alloys is designated by a symbol or symbols following the alloy designation as explained in the article entitled "Commercially Pure Wrought Aluminum."

Mechanical Properties—Typical mechanical properties of the several tempers are given in Table I.

Corrosion Resistance—The corrosion resistance of the aluminum-manganese alloy approximates that of commercially pure aluminum. This alloy frequently replaces the pure metal when somewhat greater strength is desired.

Workability—The workability of this alloy in the annealed temper (O) almost equals that of commercially pure aluminum, though for very deep drawing or severe spinning operations the latter usually is specified. In tempers up to half hard ($\frac{1}{2}$ H), the alloy is extensively used for drawn cooking utensils. In the thin gages, these tempers will take a 180° flat bend. A more liberal bend radius is necessary in the three-quarter hard temper ($\frac{3}{4}$ H), while in the hard temper (H) little forming is possible.

Welding Characteristics—The aluminum-manganese alloy is welded readily with the oxy-hydrogen or oxy-acetylene flames, the metal arc (except for thin sheets), and the common resistance welding processes. A commercially pure aluminum welding rod is used and a suitable flux must be employed. The required technique is the same as for welding commercially pure metal.

Table I
Mechanical Properties¹ of Wrought Aluminum-Manganese Alloys (3S)

Temper Designation	Tensile Strength ² Psi.	Yield Strength ³ Psi.	Elongation ⁴ , % in 2 in.	Brinell Hardness ⁵ No.	Shearing Strength ⁶ Psi.
O (Annealed)	16,000	5,000	30	28	11,000
$\frac{1}{4}$ H	18,000	15,000	10	35	12,000
$\frac{1}{2}$ H	21,000	18,000	8	40	14,000
$\frac{3}{4}$ H	25,000	21,000	5	47	15,000
H (Hard)	29,000	25,000	4	55	16,000

¹Young's modulus is approximately 10,300,000 psi. Rotating beam endurance limit (R. R. Moore type machine, 500,000,000 cycles) for 3S-O is 6,000 psi., for $\frac{1}{4}$ H is 9,000 psi. and for H is 10,000 psi.

²Stress which produces a permanent set of 0.2%. Yield strengths in tension and compression are substantially equal.

³Typical values for sheet $\frac{1}{8}$ - $\frac{1}{2}$ in. in thickness. Heavier sections, from which standard, round specimens are taken, will have higher elongations.

⁴10 mm. ball, 500 kg. load.

⁵Single shear values from double shear tests.

Annealing Practice—The fully annealed properties are obtained by heating to 775°F. for about 2 hr. and cooling in the air.

Applications and Forms—This alloy is used for architectural applications such as roofing, flashing, gutters, and doors and is used in the construction of railway cars and other vehicles for parts which are not highly stressed or forming operations not too severe. This alloy is used in the manufacture of furniture, cooking utensils, and chemical equipment. Like the commercially pure metal (2S), it is produced in the common forms such as sheet, plate, tubing, bar, rod, wire, rivets, molding, and other shapes.

*Aluminum Co. of America, Pittsburgh.

Properties of Aluminum-Silicon Alloys

By L. W. Kempf*

General—Silicon probably stands second to copper in importance as an ingredient in aluminum casting alloys. Attention was directed to the many advantageous properties of these alloys by the discovery in 1921 by A. Pacz¹ of a method of modifying their structure and thus improving their tensile properties by treating the molten alloy immediately before casting with small amounts of sodium fluoride.^{2,3} Probably the most generally valuable property of the aluminum-silicon alloys is their excellent casting qualities, including superior fluidity and freedom from hot shortness. The strength and hardness obtained on the binary alloys are not at all remarkable. Other advantages of the silicon alloys are high resistance to corrosion, low specific gravity, low thermal expansion and high conductivity for heat and electricity. The chief use of the binary alloys is in castings containing about 5-13% silicon.

Density of Solid Alloys—Edwards⁴ has determined the density of alloys containing up to about 18% silicon. The diagram in Fig. 1 presents his data. These numerical values are approximately equal to the specific gravity. The complete density curves of alloys containing 3 concentrations of silicon are given in Fig. 2.

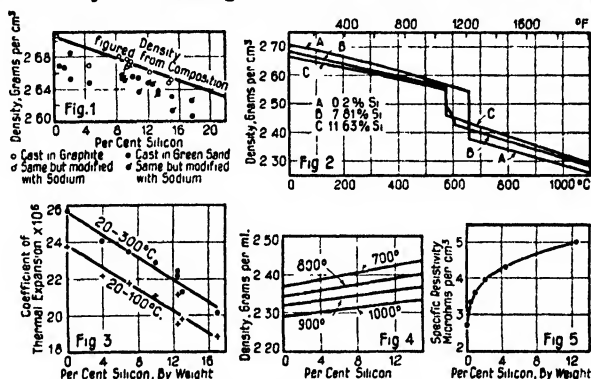

Fig. 1—Density of aluminum-silicon alloys.
Fig. 2—Density of alloys containing 3 concentrations of Si.
Fig. 3—Coefficient of expansion of Al-Si alloys.
Fig. 4—Density of liquid Al-Si alloys.
Fig. 5—Electrical resistivity of Al-Si alloys.

Thermal Expansivity—The coefficient of thermal expansion of silicon is less than $\frac{1}{2}$ that of aluminum and the aluminum-silicon alloys have appreciably lower expansivity than pure aluminum. The variation in coefficient of expansion with silicon content is indicated in Fig. 3.

Growth—The solubility of silicon in solid aluminum varies with temperature from about 0.05% at 200°C. (390°F.) to 1.65% at 577°C. (1070°F.). Alloys quenched from a high temperature solution treatment are of appreciably higher density than the same alloys in equilibrium at room temperature. The magnitude of this difference in density is small under all conditions but is greater the higher the degree of supersaturation. Thus with ordinary sand castings the rate of cooling is such that for all practical purposes, and especially for uses involving temperatures under 200°F., no changes can be detected. Changes in density have been estimated by measuring the linear change in dimensions accompanying reheating to elevated temperatures of alloys quenched from high temperature solution treatments. This change in dimension has been termed "growth" or "permanent growth." The maximum amount of growth observed in alloys containing more than about 1.7% silicon quenched from near the eutectic temperature corresponds to a unit change in lineal dimensions of 0.0016. Heating for 10-20 hrs. at 400-450°F. is required to bring about equilibrium as regards growth. The time for attainment of equilibrium varies inversely with temperature in a logarithmic manner.

*Aluminum Research Laboratories, Aluminum Co. of America, Cleveland.

Density of Liquid Alloys—The density of liquid aluminum-silicon alloys as determined by Edwards is given in Fig. 4.

Solidification Shrinkage—The percentage change in volume from a liquid at the melting point to a solid at the freezing point is known as solidification shrinkage. Edwards gives the solidification shrinkage of pure aluminum as 6.6%, that of an alloy of 7.81% silicon as 5.6%, and of an alloy of 11.63% silicon as 3.8%. The change in solidification shrinkage with silicon content is illustrated in Fig. 2.

Pattern Shrinkage—The pattern shrinkage is usually determined by casting a straight cylindrical bar between a pair of graphite or metal plates rigidly maintained a known distance apart and measuring the length of the bar when cold. Determinations by Edwards on alloys containing 12.55% and 22.4% silicon give a shrinkage of 0.16 and 0.15 in. per ft. respectively. The usual pattern shrinkage used in aluminum foundries for all aluminum alloys is $\frac{1}{32}$ in. (0.156 in.) per ft.

Electrical Resistivity—Increasing amounts of silicon increase the electrical resistivity of aluminum-silicon alloys as indicated in Fig. 5. These data are from measurements by J. D. Edwards on sand cast specimens. Some measurements by C. S. Taylor on high purity alloys in wrought form are given in Table I.

Table 1
Electrical Resistivity of High Purity Aluminum-Silicon Alloys
Iron and Copper Less Than 0.05%

% Silicon	Resistivity Microhms per cm. cube*	Resistivity, Microhms per cm. cube, annealed†
0.02 or less	2.68	2.68
0.06	2.778	2.778
0.14	2.847	2.770
0.16	2.860	2.769
0.23	2.947	2.776

*Heated 2 days at 495°C. (925°F.), quenched in cold water.

†Heated 2 days at 495°C., quenched in cold water, followed by annealing 100 days at 200°C.

Thermal Conductivity—The thermal conductivity of aluminum-silicon alloys¹ is affected in a marked manner especially at high silicon concentrations by the particle size and distribution of the silicon, the smaller the particles of silicon, the higher being the conductivity. The conductivity of sand castings in the condition of highest conductivity (annealed) decreases from about 0.39 cgs. units for the 5% silicon alloy to about 0.31 cgs. units for the 13% silicon alloy. Modification of the 13% silicon alloy with sodium increases the conductivity to 0.39 cgs. units. Similarly, the chill cast 5% silicon alloy by virtue of its fine structure has a conductivity of about 0.44 cgs. units.

Fig. 6—Tensile properties of Al-Si alloys. Sand cast test bars $\frac{1}{2}$ in. dia.

Elastic Properties—The yield strengths of aluminum-silicon alloys are generally lower than those of aluminum-copper alloys of approximately the same tensile strength. This characteristic of the silicon alloys limits their use in some applications, but it is an advantage in others where some slight bending or forming operations must be carried out on castings. Few reliable data on the elastic limit have been published, but isolated determinations and general experience would place the true elastic limit of all aluminum-silicon alloy sand castings up to 14% silicon at not over 3,000 psi. The yield strength of modified sand castings varies from about 10,000 psi. at 8% silicon to 12,000 psi. at 14% silicon. A typical yield point for the normal sand cast 5% silicon alloy is about 9,000 psi. According to the determinations of Templin and Paul² the addition of silicon to aluminum results in a fairly uniform increase of Young's modulus in tension from about 10,250,000 psi. for the 5% silicon alloys to about 11,100,000 psi. for an alloy containing 13% silicon.

Tensile Properties—Fig. 6 gives the tensile properties of both normal and modified aluminum-silicon alloys in the form of $\frac{1}{2}$ in. dia. sand cast test bars.¹ These values represent laboratory determinations and the values given for modified alloys are those for material in which special care was taken to obtain the optimum effects of the modification process. Fig. 7 indicates the variation in tensile properties with silicon content of chill cast test bars.¹ Fig. 8 gives the tensile properties of 0.08 in. thick aluminum-silicon sheet in the hard rolled and annealed conditions.

Shearing Strength—The ultimate strength in double shear of the 5% silicon normal sand cast alloys is about 15,000 psi. For the modified 13% silicon alloy the shearing strength is about 18,000 psi.

Fatigue Resistance—Endurance limits for cast aluminum-silicon alloys containing from 5-14% silicon as given in the literature vary between 5,700 psi. and 9,500 psi. Results are not very concordant and the determinations were made on the basis of 5-50 millions of reversals. Determinations made in the Aluminum Research Laboratories on the basis of 500,000,000 cycles with the R. R. Moore type of rotating beam machine place the endurance limit of the normal sand cast 5%

Fig. 7—Variation in tensile properties with Si content—chill cast test bars.

Fig. 8—Tensile properties of Al-Si sheet.

Fig. 9—Impact properties of Al-Si alloys.

silicon alloy at about 6,500 psi. The value for the modified 13% silicon alloy is about 6,000 psi.

Impact Properties—Fig. 9 from the data of Grogan⁸ and Stockdale⁹ gives the variation of impact resistance with silicon content of some modified sand and chill cast alloys.

Corrosion Resistance—Comparative experience in various fields indicates that the aluminum-silicon alloys preserve a better appearance under the conditions of ordinary atmospheric corrosion than do the aluminum-copper alloys. The rate of loss in mechanical strength of either of the types of alloys under these conditions is very low. Under conditions of salt spray corrosion, aluminum-silicon alloys appear to be definitely superior to the aluminum-copper alloys or the aluminum-copper-zinc alloys. They are, however, inferior under these conditions to the aluminum-magnesium alloys. Czocharski¹⁰ presents data on relative loss in weight in steam and nitric acid of the modified 13% silicon alloy, the 8% copper alloy, and the 12% zinc-2% copper alloy. All alloys were in the cast condition. Under these conditions the 13% silicon alloy is superior to the 8% copper, and the 12% zinc-2% copper alloys.

Casting Properties—The aluminum-silicon alloys are especially fluid, fill molds better, and take sharper impressions than any of the other common alloys of aluminum. For the normal alloys, the fluidity increases with silicon content up to the composition of the eutectic, about 11.6% silicon, and about 12-14% silicon for the modified alloys. Alloys containing upwards of about 3% silicon and with iron and copper in concentrations usual in ordinary commercial virgin ingot are unusually

free from hot shortness. This valuable property improves with increasing silicon content up to the eutectic composition, but all of the alloys containing from 5-13% silicon can be cast readily without cracking. The 5% silicon alloy is comparatively easy to feed, but as the silicon increases the alloys become subject to a peculiar type of internal shrinkage, and careful feeding is necessary in the case of alloys of high silicon contents. The ratio volume of risers to volume of castings should, in general, be greater in the case of the 13% silicon alloys than in the case of the 8% copper alloy. Because of their freedom from hot shortness and the characteristic tendency to form a sound outer layer or skin, the aluminum-silicon alloys are especially suitable for the production of castings which must be free from leaks.

Welding Rod—Some of the properties which make the aluminum-silicon alloys so valuable in the castings field have also been responsible for their wide use as welding rod. An alloy containing about 5% silicon is widely used for welding both cast and wrought products. Such rod is utilized in the cast and wrought forms, depending on the personal preference of the operator and the type of welding being done.

Properties of Aluminum-Silicon (13%) Casting Alloys

By H. J. Rowe*

An aluminum-silicon alloy containing silicon in excess of the normal eutectic value,† if properly modified or treated prior to casting to insure solidification without the separation of visible particles of primary silicon, possesses mechanical properties considerably in excess of those obtained with an alloy of low silicon content. This modification may be produced by rapid cooling as in the die casting process** or, if sand cast, by the controlled addition of certain modifying agents such as sodium.†† The most common alloy of this type contains approximately 13% silicon with the balance aluminum. The properties of this alloy are as follows:

Physical Properties of Aluminum-Silicon Alloys (13% Si)

	Sand Cast	Die Cast
Ultimate tensile strength, psi. (min. to average ¹)	24,000-26,000	28,000-33,000
Yield strength, psi. (average ¹)	11,000	18,000
Elongation, % in 2 in. (min. to average)	5.0-8.0	1.0-2.0
Brinell hardness, 10 mm. ball, 500 kg. load	45-60	65-80
Rockwell hardness, 1/8 in. ball, 100 kg. load	E48-E72
Yield strength in compression, psi. (approx. ^{2,3})	11,000
Shearing strength, psi. (approx. ⁴)	18,000
Charpy impact resistance, ft.-lb. (approx. ⁵)	3.0	2.0
Endurance limit, psi. (approx. ⁶)	6,000	15,000
Modulus of elasticity, psi. (approx.)	10,300,000	10,380,000
Specific gravity (approx.)	2.66	2.66
Weight per cu. in., lb. (approx.)	0.096	0.096

General Properties and Uses—The modified 13% silicon alloy has found considerable application in Europe, and in this country in certain foundries where heat treating equipment for the production of high strength heat treated alloys is not available. Such alloys as "Silumin" and "Alpax," both of this general composition, are still being used extensively in foreign foundries. However, with the newer heat treated alloy developments in this country,† the modified 13% silicon alloy is rapidly being replaced for sand casting work.

If proper care is taken during alloying and modification to prevent excessive oxidation, this alloy possesses many of the same desirable casting characteristics as does the 5% silicon alloy. It casts well in intricate, thin sections requiring pressure tightness, and has very good corrosion resistance. Since the beneficial effect of the modification process is largely lost on the remelting of this alloy, a retreatment of the metal is necessary if the resulting castings are to possess the properties of the modified alloy. The machinability of the 13% silicon alloy, as judged by the surface finish, is not so good as that of the aluminum-copper alloys.

The 13% silicon alloy is used for marine, automotive, steam radiators, water jackets, and manifold castings. For die castings, the 13% silicon alloy is generally preferred for large intricate castings with thin sections, because it combines good mechanical properties with excellent casting characteristics.

Properties of Aluminum-Silicon (5%) Casting Alloys

By H. J. Rowe*

Aluminum-silicon alloys, because of their exceptional casting characteristics in intricate castings, find a large field of application. Such alloys, containing from 3-12% silicon,[†] are quite fluid at temperatures almost down to the freezing point and have a lower solidification shrinkage than the common aluminum-copper alloys. This combination of properties, together with excellent corrosion resistance, makes aluminum-silicon alloys particularly well suited for the production of dense, leak-proof castings, resistant to corrosive conditions. The properties of the most common of these alloys, one containing approximately 5% silicon and 95% aluminum, are as follows:

Physical Properties of Aluminum-Silicon (5%) Casting Alloy

General Properties and Uses—In addition to the casting characteristics and corrosion resistance, the 5% silicon alloy also possesses fair mechanical properties suitable for many engineering applications. The yield strength-tensile strength ratio is, however, somewhat lower than that of the common aluminum-copper alloys, and the machinability inferior because of the tendency of tools to drag the surface. This latter property can be materially overcome with the proper tool set-up. To insure maximum corrosion resistance, it is quite essential that a minimum of impurities be maintained in this alloy.

The properties of the 5% silicon alloy are ideal for use in marine castings, manifolds, water jackets, aircraft fittings, automotive body sections, meter cases, miscellaneous thin sections, and intricate castings where a minimum of machining is required and the mechanical properties are adequate. This alloy is also especially suited for architectural and ornamental castings of thin sections which require fine sharp details and which are subject to continuous atmospheric exposure. The 5% silicon alloy is likewise readily cast in permanent molds and dies.

Properties of Aluminum-Magnesium-Chromium Alloy

By F. Keller*

General Description—The aluminum-magnesium-chromium alloy designated "52S" has moderate strength combined with good resistance to corrosion, good workability, and high fatigue resistance. It is not susceptible to solution heat treatment, but can be strengthened and hardened by cold working.

Physical Properties—The sp.gr. of the alloy is 2.67. One cu.in. weighs 0.096 lb. The electrical conductivity, expressed in percentage of the "International Copper Standard", is 35. The thermal conductivity at 100°C. in cgs. units is 0.32.

Composition—The alloy has the following nominal composition: Magnesium, 2.5%; chromium, 0.25%; and aluminum, plus normal impurities, the balance.

Temper Designation—Only the annealed, intermediate, and hard rolled tempers of this alloy are produced. The temper is designated by a symbol or symbols following the alloy designation as explained in the article entitled "Commercially Pure Wrought Aluminum".

Mechanical Properties—The tensile and yield strength of this alloy is appreciably higher than for commercially pure wrought aluminum and wrought aluminum-manganese alloys. In the hard rolled temper, the alloy has a yield strength comparable with that of the heat treated strong aluminum alloys. Typical mechanical properties of this alloy in its various tempers are given in Table I.

Resistance to Corrosion—All of the tempers of this alloy have excellent resistance to corrosion. This alloy is particularly resistant to corrosion by salt water.

Workability—The alloy has good workability and in the annealed temper it is suitable for severe drawing and forming operations. The workability of the intermediate and full hard tempers decreases in proportion to the amount of cold reduction similar to other cold worked aluminum alloys.

Welding Characteristics—The methods commonly employed for welding other aluminum alloys can be used successfully. The torch welding characteristics are fair, while the resistance welding characteristics are excellent.

Annealing Treatment—This alloy can be annealed by heating to a temperature of 750°F., after which it should be withdrawn from the furnace and cooled in air.

Forms Produced—The forms in which this alloy is available are: Sheet, plate, wire, rod and bar, tubing and pipe.

Applications—This alloy finds general application for formed articles, for marine applications, and for structural uses where good workability, moderate mechanical properties, high fatigue strength, and good resistance to corrosion are desired.

Table I
Typical Mechanical Properties of Aluminum-Magnesium-Chromium Alloy¹ (52S)

Temper	Yield Strength ¹ (Set = 0.2%) Psi.	Ultimate Strength, Psi.	Elongation, ² % in 2 in. Sheet Specimen ($\frac{1}{8}$ in. Thick)		Round Specimen (0.505 in. Dia.)	Brinell Hardness 500 Kg. Ball 10 Mm. Ball	Shearing Strength ⁴ , Psi.	Endurance Limits ⁵ , Psi.	Approx. Radii for 90° Cold Bend ⁶

¹Young's modulus of elasticity is approximately 10,300,000 psi.

²Stress which produces a permanent set of 0.2% of the initial gage length. (A.S.T.M. Specification, Methods of Tension Testing, E 8-33.)

³Elongation values vary with the form and size of tension test specimen. Thin sheet has somewhat lower elongation than values for $\frac{1}{8}$ in. sheet shown in table. Thicker material, from which standard round tension test specimens (0.505 in. dia.) are tested, may have lower elongation because of the effect of commercial flattening operations on this property.

⁴Single shear strength values obtained from double shear tests.

⁵Based on withstanding 500,000,000 cycles of completely reversed stress, using the R. R. Moore type of machine and specimen.

⁶Bend radii expressed in terms of t =thickness of sheet. The minimum radii varies with the nature of the forming operation, type of forming equipment, and design and condition of tools, and with the thickness of the material.

*Aluminum Research Laboratories, New Kensington, Pa.

Properties of Aluminum-Copper-Iron-Magnesium Alloy Cast in Permanent Molds

By O. H. Heil*

This class of alloys was first developed for use in automotive pistons. Castings for this type of service are usually made in cast iron molds with steel cores. The rapid solidification results in mechanical properties appreciably higher than are obtained when the same alloy is cast in sand molds. Although slight modifications have been made in the original chemical composition (approximately 10% copper, 1% iron, and 0.25% magnesium¹) from time to time, the essential characteristics of the alloy have not been changed. Considerable improvement has been achieved by means of heat treatments, which can be grouped into two classes. Typical values for physical properties of the two classes are given in Table I.

Under "A" are listed properties for a typical high temperature solution heat treatment, followed by quenching and aging at a lower temperature. This type of treatment yields the highest combination of hardness and toughness. Other heat treatments of this type, with slight variations in time and temperatures used, result in slight changes of some of the figures quoted.

The rapid solidification accompanying casting in chill or "permanent" molds makes possible appreciable increases in hardness by "aging" or low temperature treatments alone. Hardness increases obtained in this manner are accompanied by corresponding decreases in toughness. It may be noted that values for Charpy impact resistance and percentage elongation are identical for the "A" and "B" treatments. This should not be interpreted as indicating equivalent toughness. Considerable data exist in the form of slow bend tests and practical experience indicates that for equivalent hardness the "A" treatment yields a product considerably tougher than the "B" treatment. Under "B" of the above table are

Fig. 1—Tensile properties of aluminum-copper-iron-magnesium (122) alloy at elevated temperatures. Brinell hardness at room temperature following stabilizing and testing at elevated temperatures.

listed typical properties for this type of treatment. Changes in time and temperature here will also result in slight deviations of some of the properties from those mentioned in the table.

General Properties and Uses—Alloys of this type combine satisfactory casting properties, good machining characteristics, and good mechanical properties at piston operating temperatures. Fig. 1 gives the variation with temperature of the tensile properties of specimens cast in permanent molds and originally in the "B" condition. Before testing, the specimens were held (40-150 days) at the temperature being investigated until no further change in properties could be detected. The Brinell hardness was determined at room temperature after stabilizing and testing at the elevated temperature.

In addition to its primary use in pistons, this alloy is utilized in other places where good machinability, high hardness and wear resistance are desired. Such applications are valve guides, typewriter parts, and sole plates for flatirons.

Properties of Aluminum-Copper-Magnesium-Manganese Alloy

(17S or Duralumin)

By P. V. Faragher*

General—An aluminum-copper-magnesium-manganese alloy, commonly called 17S or duralumin, is the oldest of the duralumin type alloys, several of which are now in commercial production. Some of the newer alloys possess definite advantages for certain purposes, but this alloy is still generally used in a great variety of products. For applications requiring good forming capacity and for which lower physical properties are acceptable, a modified composition designated A17S is available. This alloy is being used extensively in rivets because they can be driven in the fully heat treated and aged temper.

Composition—These alloys have the following nominal compositions in per cent:

	17S	A17S
Copper	4.0	2.5
Magnesium	0.5	0.3
Manganese	0.5	...
Aluminum plus normal impurities*.....	Remainder	Remainder

*Iron and silicon are always present in commercial aluminum ingot used in the manufacture of these alloys in amounts up to a max. of 1%. The silicon is an essential constituent of the alloy in the amounts normally present.

Specific Gravity—The sp.gr. of these alloys and their density in lb. per cu.in. are as follows:

	17S	A17S
Sp. gr.....	2.79	2.74
Density, lb. per cu.in.....	0.101	0.099

Temper Designation—These alloys are designated by the principal manufacturer by a number, followed by the letter "S" to indicate that they are wrought products. The number may be preceded by a letter to indicate a modification of the original alloy composition, such as A17S. The letter or letters designating the temper follow the alloy symbol, separated from it by a dash.

The "soft" or "annealed" temper is designated by the letter "O"; the heat treated temper by the letter "T"; and the temper resulting from cold working the material after heat treatment by the letters "RT". There is but one heat treated temper, since these alloys age harden at room temperatures.

Physical Properties—Typical mechanical properties of these alloys are shown in Table I. (Obviously these typical average values cannot be used as minimum values for purchase specifications.)

Table I

Typical Mechanical Properties of Aluminum-Copper-Magnesium-Manganese Alloys

Alloy	Temper	Tensile Strength, psi.	Yield Strength, psi.	Elongation, % in 2 in.	Shear Strength, psi.
17S	O	26,000	10,000	20	18,000
17S	T	60,000	37,000	20	36,000
17S	RT	65,000	47,000	13	38,000
A17S	O	22,000	8,000	24	15,000
A17S	T	43,000	24,000	24	25,000
Alclad 17S	T Sheet	56,000	33,000	18	32,000
Alclad 17S	RT Sheet	57,000	40,000	11	32,000

Corrosion Resistance—These alloys present considerable resistance to corrosion under most atmospheric conditions, but as a precaution, it is common practice in structural work to apply protective paint coatings. For severe conditions (under exposure to salt spray) sheet and wire are available with a core of 17S alloy and surfaces of pure aluminum, or of a highly corrosion resistant alloy which is anodic to the base alloy. The surface layers are alloyed and integral with the underlying

*Metallurgical Department, Fabricating Division, Aluminum Co. of America, Pittsburgh.

17S core and protect it, both by preventing contact with the corrosive medium, and by electrolytic action: Thus protected, sheet and wire are sold under the trade marked name "Alclad".

Workability—In the soft temper these alloys can be subjected to severe forming operations. In the fully heat treated temper, greater radii are required for bends, and less depth of drawing is possible than in the soft temper or immediately after quenching. The modified composition, A17S-T, withstands more severe working than 17S-T. By choosing proper radii for bends and suitable tools, 17S-RT can be formed into various structural shapes without difficulty. If 17S is quenched from the heat treating temperature and formed in less than 2 hrs. before aging occurs, it is only slightly less workable than in the soft temper. By storing at a temperature below 32°F., greater workability can be retained for a day or more. "Alclad" sheet can be bent around a smaller diameter than uncoated sheet of the same gage and temper.

Welding—Spot welding is coming into use for joining these alloys in the gages for which this process is applicable. They can be welded by the torch and arc welding processes, but the mechanical properties and resistance to corrosion of the metal adjacent to the welds are lowered and must be restored by heat treatment of the assembly. The cast metal in the weld does not develop as high properties as the wrought alloy, which fact must be considered when designing the joint. Other methods of joining are commonly used.

Heat Treatment—These alloys are heat treated by heating at a temperature of 930-950°F. The time of heating varies with the thickness of the metal and the heating medium. After heating, the alloy is quenched in cold water. The interval between removing the metal from the heating medium and completely immersing it in the water should be as short as possible, at most several seconds. Aging takes place at room temperature, the rate gradually decreasing for about four days when it is practically completed. Aging may be retarded by cooling the alloys below 32°F., but it proceeds at the normal rate when they are warmed to room temperature. "Alclad" material should be heated the shortest length of time which will produce desired properties. If Alclad sheet is heated too long there will be too great diffusion of the alloying elements of the core into the surface layer, with consequent injury to the protecting qualities of the latter.

Annealing—The annealing practice varies with the condition of the alloy and the result desired.

(a) Material originally in the soft temper which has been hardened by cold forming, can be annealed completely by heating it to 640-670°F., and cooling.

(b) Material in the heat treated temper, whether subsequently cold worked or not, will have most of the effects of heat treatment removed by following the practice described in paragraph (a). For severe forming which requires completely softened material, the following practice is necessary.

(c) For the complete annealing of alloys in the heat treated (T) temper, whether or not they have been subsequently strain hardened, heat the metal for 2 hr. at a temperature of 750-800°F., and then cool slowly. The rate of cooling to 500°F. should not exceed 50°F. per hr. The rate of cooling below 500°F. is unimportant.

Commercial Forms—The alloy 17S is available commercially in all of the usual wrought forms such as sheets, plates, tubes, rods, bars, wire, rolled and extruded shapes, forgings, rivets, bolts, nuts, machine screws, and other screw machine products. The alloy A17S is produced only in rivets.

Properties of Wrought Aluminum-Copper-Magnesium (1.5%) Manganese Alloy

By T. W. Bossert* and J. A. Nock, Jr.†

General—The aluminum-copper-magnesium-manganese alloy, known as 24S, is a heat treatable wrought aluminum alloy having mechanical properties superior to those of 17S with workability slightly inferior to that of 17S in the "T" and "RT" tempers. The alloy was developed particularly for the aircraft field. After solution heat treatment, the alloy age hardens spontaneously at room temperature. Like 17S, this alloy may be had in the Alclad¹ form.

Composition—The nominal composition of the alloy is copper 4.4%, magnesium 1.5, manganese 0.6, and balance aluminum.

Specific Gravity—The specific gravity of this alloy is 2.76.

Temper Designation—The temper in which this alloy is supplied is designated by a symbol or symbols following the alloy designation.

In both bare and Alclad form, this alloy is supplied in three tempers; namely, annealed, designated by the suffix "O"; heat treated and aged (at room temperature), designated by the suffix "T"; and heat treated, aged, and cold worked a definite amount, designated by the suffix "RT".

Mechanical Properties—Typical mechanical properties for both the bare and Alclad forms are given in Table I.

Table I
Properties of 24S Aluminum Alloy

Temper	Tensile Strength, psi.	Yield Strength, psi.	Elongation, % in 2 in.	Brinell Hardness	Shear Strength, psi.	Endurance Limit* psi.
-O	26,000	10,000	20	42	18,000	12,000
-T	68,000	44,000	19	105	41,000	18,000
-RT	70,000	55,000	13	116	42,000

Alclad 24S Sheet

-O	25,000	10,000	18
-T	62,000	41,000	18	..	40,000
-RT	66,000	50,000	11	...	41,000

*Based on the material withstanding 500 million cycles of stress.

Corrosion Resistance—The maximum corrosion resistance of both forms of this alloy is developed in the heat treated, or in the heat treated and rolled tempers. These materials are not intended for use in the annealed temper, but the metal may be obtained in this temper for drawing or for severe forming operations which are then followed by heat treatment.

The bare alloy has a corrosion resistance which is similar to that of 17S. The same protective measures against corrosion that apply to 17S should be observed in using 24S.

The Alclad form of the alloy has, because of the pure aluminum coating, excellent corrosion resistance and can generally be used without additional protective coating.

Workability—In the annealed temper both forms of this alloy are reasonably workable. The material can be formed over sharp radii and can be drawn to a limited extent. Annealed material is, therefore, often specified and the material, after working, is heat treated to develop its characteristic properties. The heat treated tempers of these materials are not suitable for drawing, but can be formed over a bend radius equal to 1-6 times² the material thickness. This alloy is more

*Fabricating Division, Aluminum Co. of America.

†Aluminum Research Laboratories, New Kensington, Pa.

¹The Alclad form of 24S alloy consists of the high strength core covered on both sides with a layer of high purity aluminum.

²The multiple bend radius increases from 1-6 times the thickness as the thickness of the piece itself increases.

workable immediately after quenching and the more difficult bends may be made in this manner.

Welding—This alloy, and particularly Alclad 24S, may be satisfactorily welded by electric resistance methods. It is not suitable, however, for torch or arc welding.

Solution Heat Treatment—The solution heat treatment of all forms of this alloy consists of heating the stock to 915-930°F. in a fused nitrate bath or suitable air furnace. The time at this temperature is determined by the thickness of the section. The alloy is quenched in cold water with the minimum of delay between removal from the heat treating medium and immersion in the quenching water.

No elevated temperature aging is required for this alloy, as the material develops its normal heat treated properties by spontaneous aging; in fact, such elevated temperature aging is to be avoided.

Annealing—The alloy is annealed by heating to 650°F. for about 2 hr. and then cooling normally in air.

Forms Produced—This alloy is available in the form of sheet, rod, bar, extruded shapes, tubing, rivets, and wire. The Alclad form of this alloy is furnished in sheet form only.

Applications—Both forms of this alloy are used where maximum strength is desired with minimum weight. Its use in aircraft construction particularly is indicated, but its applications are not entirely limited to this field.

Properties of Aluminum-Copper-Nickel-Magnesium Alloy Cast in Permanent Molds

By O. H. Hell*

This alloy, sometimes known as "Y" alloy,¹ finds its most extensive use in this country in the form of castings for aircraft and Diesel motor pistons. To a lesser extent it is used for outboard motor pistons. Castings for this type of service are usually made in cast iron molds with either steel or sand cores. The rapid solidification results in mechanical properties appreciably higher than are obtained

when the same alloy is cast in sand molds. The nominal chemical composition is 4% copper, 2% nickel, and 1.5% magnesium. The piston castings are usually heat treated. The heat treatments used can be grouped into two classes. Typical values for physical properties of the two classes are given in Table I.

Under "A" are listed properties for a high temperature solution heat treatment followed by quenching and aging at a lower temperature. This treatment yields the highest combination of hardness and toughness.

The rapid solidification accompanying casting in chill or "permanent" molds makes possible appreciable increases in hardness by "aging" or low temperature treatments alone. Hardness increases obtained in this manner are accompanied by corresponding decreases in toughness. Under "B" of the above table are listed properties for this type of treatment.

General Properties and Uses—Heat treating effects in this alloy are unaccompanied by appreciable changes in density. This distinctive property is of value in structures, such as pistons, operating at elevated temperatures, since it insures practical stability of dimensions, other than the normal thermal expansion and contraction, regardless of the structural condition of the alloy. Fig. 1 shows the

variation with temperature of the tensile properties of chill cast test bars of this alloy. The bars were originally in the "B" condition and were held at the temperature of testing until no further change in properties could be noted. The holding periods varied from 40-150 days. The Brinell hardness determinations were made at room temperature after the tensile tests at elevated temperatures.

Properties of Wrought Aluminum-Magnesium-Silicon Alloys

By F. Keller* and T. W. Bossert†

General—The aluminum-magnesium-silicon alloy (53S) is susceptible to solution heat treatment.^{1,2} It is formed easily and can be welded in the annealed and heat treated tempers. The alloy finds a wide field of application where moderate strength, good workability, and high resistance to corrosion are of prime importance. It is available in the form of sheet, plate, extruded shapes, tubing, rod, bar, wire, and rivets.

Composition—The alloy has the following nominal composition:

Silicon	0.7%
Magnesium	1.2%
Chromium	0.25%
Maximum total of other elements.....	0.55%
Aluminum	Balance

Specific Gravity—The specific gravity of the alloy is 2.69.

Temper Designations—The temper of wrought aluminum alloys is designated by a symbol or symbols following the alloy designation as explained in the article entitled "Commercially Pure Wrought Aluminum."

Mechanical Properties—Typical mechanical properties of the alloy in various tempers are given in Table I.

Resistance to Corrosion—The alloy in all of its various tempers shows excellent resistance to weathering and corrosion and is particularly suitable for those applications where such characteristics are essential.

Workability—The annealed temper of this alloy is adapted for severe drawing and forming operations. The workability of the intermediate and full hard tempers is decreased in proportion to the amount of cold reduction and the softer intermediate tempers have excellent working characteristics. After a solution heat treatment the alloy possesses satisfactory workability for all but the more severe drawing or forming operations. Precipitation heat treatment decreases the workability, but may be accomplished after forming the heat treated material without causing distortion.

Table I
Mechanical Properties¹ of Aluminum-Magnesium-Silicon Alloy

Temper Designation	Tensile Strength, psi.	Yield Strength, ² psi.	Elongation, % in 2 in.	Brinell Hardness ³ No.
O (Annealed)	16,000	7,000	25	26

T ⁶	28,000	20,000	14	54
T5 ⁶				

¹Young's Modulus is approximately 10,000,000 psi.

²Stress at which stress strain curve departs 0.2% from the initial modulus line produced.

³10 mm. ball, 500 kg. load.

⁴Temper produced by solution heat treatment.

⁵Temper produced by precipitation heat treatment.

⁶Special temper available only in extruded forms.

Welding Characteristics—This alloy can be welded by the methods commonly used for welding the other aluminum alloys.

Heat Treatment and Aging—The recommended temperature range for the solution heat treatment is 960-980°F. The preferable precipitation heat treatment consists in heating for 18 hr. at 310-320°F.

Annealing Treatment—The practices commonly employed for annealing other aluminum alloys are suitable for this material.

²E. H. Dix, Jr., F. Keller, and R. W. Graham, Equilibrium Relations in Aluminum-Magnesium-Silicon Alloys of High Purity, Trans., A.I.M.E., Inst. Metals Div., 1931, v. 93, p. 404.

Properties of Wrought Aluminum-Manganese-Magnesium Alloy

By T. W. Bossert* and J. A. Nock, Jr.†

General Description—The aluminum-manganese-magnesium alloy, known as 4S,¹ is a moderate strength alloy with good workability and very good corrosion resistance. It is not susceptible to hardening by heat treatment. In its harder tempers the yield strengths approach those of the strong heat treatable alloys, although the ultimate strengths are lower.

Specific Gravity—The specific gravity of this alloy is 2.72.

Composition—The nominal composition of the alloy is magnesium 1%, manganese 1.25% and the balance aluminum.

Temper Designation—This alloy is produced only in the annealed, intermediate and hard rolled tempers.

Tempers of aluminum alloys are designated by a symbol or symbols following the alloy designation. Thus the annealed temper is designated by the suffix "O", and the hard rolled temper by the suffix "H". Intermediate tempers are designated by fractions preceding the letter "H". The intermediate and hard rolled tempers are produced by cold working the alloy to definite extents after annealing.

Characteristics—Typical mechanical properties for the various tempers of the alloy are given in the following tabulation:

Temper	Tensile Strength, psi.	Yield Strength, psi.	Elong., % in 2 in	Brinell Hardness No.	Shear Strength, psi.	Endurance Limit, psi.
4S-O ...	26,000	10,000	20	45	16,000	14,000
4S-1/4H .	31,000	22,000	10	52	17,000	14,500
4S-1/2H .	34,000	27,000	9	63	18,000	15,000
4S-3/4H .	37,000	31,000	5	70	20,000	15,500
4S-H	40,000	34,000	5	77	21,000	16,000

Corrosion Resistance—The corrosion resistance of the aluminum-manganese-magnesium alloy is of the same order for all tempers, and is similar to that of commercially pure aluminum.

Workability—The annealed temper of this alloy will normally withstand drawing and forming operations of average severity. It will not form as readily as commercially pure aluminum. The workability decreases with increase of hardness, so that the full hard temper is suitable for but little drawing work, and requires rather generous bend radii.

Welding—This alloy can be joined by welding, using common commercial practice for aluminum and its alloys. To avoid cracking, care must be exercised in torch welding heavy sections.

Annealing—This alloy is annealed by heating to a temperature of 750°F., after which it should be withdrawn from the furnace and cooled in air.

Forms Produced—This alloy is furnished in sheet, plate, tubing, rod, bar, extruded shapes, wire, and rivets.

Applications—This alloy finds general application in the field of formed articles where medium strength, resistance to deformation and good corrosion resistance are important.

Its harder tempers are particularly applicable where lightness, high corrosion resistance, and resistance to permanent deformation are required, as in panel and siding stock.

Properties of Heat Treated Aluminum-Silicon-Copper-Magnesium Casting Alloys

By L. W. Kempf* and H. J. Rowet†

One of the alloys developed in the attempts to improve the mechanical properties of the binary aluminum-silicon alloys contains about 5% silicon, 1.25% copper, and 0.5% magnesium.^{1,2} This alloy retains the excellent casting characteristics of the binary aluminum-silicon alloys containing from 5-10% silicon and in addition is capable of developing by heat treatment superior mechanical properties. Castings of this alloy are produced with a number of different heat treatments. Some of the mechanical and physical properties obtained with each of these heat treatments are given in Table I.

General Properties and Uses—This alloy was developed for a rather specific field of application; namely, that of liquid cooled cylinder heads for internal combustion motors. It possesses the casting characteristics necessary for the economical production of castings of such complicated nature. Pressure tight castings are more easily produced than in any other casting alloy suitable for this purpose. The alloy maintains its mechanical properties well at temperatures in the neighborhood of 400°F. Thus short time tensile tests performed at 400°F. after extended exposure to that temperature gave average values of 18,000 psi. tensile strength and 3% elongation on metal originally in the "B" condition. Its corrosion resistance is not so good as that of the copper-free heat treated aluminum-silicon-magnesium alloy or that of the 5% aluminum-silicon alloy.

Various heat treatments as listed in the table of properties have been developed to provide a combination of properties satisfactory for many types of service. Where good strength, excellent ductility and toughness are desired, the high temperature solution heat treatment "A" is indicated. If higher hardness, yield and tensile strengths are more desirable than maximum ductility, the solution heat treatment should be followed by a precipitation treatment (B). An extended precipitation treatment following a solution treatment yields maximum hardness, yield and tensile strengths with correspondingly low elongation (C). A special heat treatment "D" consisting in a precipitation treatment alone has been developed for complicated castings with large variations in cross sectional area. If it is desirable to essentially stabilize the alloy as regards slight changes in density on reheating, a special precipitation heat treatment "E" may be applied.

This alloy has been successfully utilized in producing castings for liquid-cooled cylinder heads for automotive, aircraft, and Diesel engines, for water jackets, cylinder blocks and water-cooled exhaust manifolds.

The excellent casting characteristics of this alloy make it especially adaptable to the production of permanent mold castings. Castings so produced will show mechanical properties considerably higher than those of the same alloy cast in green sand.

Properties of Heat Treated Aluminum-Silicon-Magnesium Casting Alloy

By L. W. Kempf* and H. J. Rowe†

The many advantages of the binary aluminum-silicon alloys for castings are accompanied by the disadvantage of relatively low strength. Attempts to overcome this disadvantage have led to the development of several heat treated alloys, one of which contains about 7% silicon and 0.3% magnesium.¹ When made of metal of sufficiently high purity, this alloy, following the proper heat treatment, develops tensile properties quite comparable with those of the heat treated aluminum-copper casting alloys. Table I gives the mechanical and physical properties of this type of alloy.

General Properties and Uses—The casting characteristics of this type of alloy are fully equal to those of the binary aluminum-silicon alloys containing from 5-10% silicon. With a high temperature solution heat treatment (A) the alloy possesses the maximum combination of strength and ductility and this is the heat treatment to be used where toughness or shock-resisting ability is desired. If high hardness, yield and tensile strengths are more desirable than maximum ductility, the solution treatment is followed by a precipitation treatment (B). The corrosion resistance

*Aluminum Research Laboratories, Aluminum Co. of America, Cleveland.

†Technical Department, Castings Division, Aluminum Co. of America, Cleveland.

¹R. S. Archer and L. W. Kempf, Aluminum-Silicon-Magnesium Casting Alloys, Trans., A.I.M.E., Inst. of Metals Div., 1931, v. 93, p. 448.

of this alloy is somewhat superior to that of other commercial aluminum alloys containing substantial concentrations of copper.

This alloy has been used quite successfully in the same type of castings that have been produced satisfactorily from the heat treated 4% copper alloy. There are, however, inherent differences in the two types of alloys which should be noted. The aluminum-copper alloy with a solution heat treatment possesses a higher impact resistance than the aluminum-silicon-magnesium alloy under the same conditions. On the other hand, the aluminum-silicon-magnesium alloy has a corrosion resistance superior to that of the aluminum-copper alloy and also casting characteristics which are very much better. The latter permit the production of complicated or pressure tight castings which might be impractical in the heat treated aluminum-copper alloys. Such parts as automotive and Diesel engine crankcases, engine bases, transformer connector cases, and miscellaneous pneumatic tools and air compressor parts might be cited as suitable applications for the heat treated aluminum-silicon-magnesium alloy. The machinability of this type of alloy is quite satisfactory, being much better as regards surface finish than that of the binary un-heat treated aluminum-silicon alloys.

The excellent casting characteristics of this alloy make it quite adaptable to casting in permanent molds, and when so produced castings have mechanical properties considerably higher than when cast in sand.

Properties of Aluminum-Silicon-Nickel-Copper-Magnesium Alloy

(132 AND 32S)

By L. W. Kempf* and O. H. Heilt

This class of alloys was developed to meet the demand for a material with a lower coefficient of thermal expansion than the older alloy in general use for automotive pistons which contains about 10% copper. A preferred composition is 12-14% silicon, 1% copper, 1% magnesium, and 1-2% nickel.¹ Typical values for physical properties of the three classes of heat treatments are given in Table I.

Under "A" are listed properties for castings with a typical high temperature solution heat treatment followed by quenching and aging at a lower temperature. This type of treatment yields the highest combination of hardness and toughness. Other heat treatments of this type, with slight variations in time and temperatures used, result in slight changes of some of the figures quoted.

The rapid solidification accompanying casting in chill or "permanent" molds makes possible appreciable increases in hardness by "aging" or low temperature treatments alone. Hardness increases obtained in this manner are accompanied by corresponding decreases in toughness. Under "B" of Table I are listed typical properties for this type of treatment. Changes in time and temperature here will also result in slight deviations of some of the properties from those mentioned in the table.

Under "C" are listed typical properties of this type of alloy in the forged, solution heat treated, and aged condition. A large proportion of the aircraft pistons are now being produced by this process.

Fig. 1—Tensile properties of chill cast aluminum-copper-magnesium-nickel-silicon (132) alloy at elevated temperatures. Brinell hardness at room temperature after stabilization and testing at elevated temperatures.

General Properties and Uses—In addition to the relatively low coefficient of thermal expansion, this alloy possesses other properties which recommended its use for pistons. These are low specific gravity, which makes it especially acceptable to the aircraft industry, high hardness and excellent bearing properties. Like the aluminum-copper piston alloys, it retains a large percentage of its mechanical properties at the elevated temperatures existing in internal combustion motor pistons as is evident from Fig. 1. The test specimens used in determining the properties on which these curves are based were cast in permanent molds and originally in the "B" condition were held at the temperature of testing until no further change in properties could be noted. The holding periods varied from 40-150 days. The Brinell hardness determinations were made at room temperature after the stabilization and testing at elevated temperatures.

The machining properties of this alloy are not equal to those of the aluminum-copper alloys. With the use of tungsten carbide tools, however, large quantities of these pistons are being machined without difficulty.

This alloy possesses casting characteristics differing from those of the older aluminum-copper piston alloys. One of the most important is its greater tendency toward internal shrinkage in heavy sections. A casting technique has been developed which overcomes this tendency and makes possible the quantity production of sound castings.

Properties of Wrought Aluminum-Silicon-Magnesium Alloy

L. W. Kempf* and J. H. Alden**

General—An aluminum-silicon-magnesium alloy (51S†) is widely used in the wrought form. It is characterized by excellent hot workability and is susceptible to heat treatment. It can be coldformed easily, particularly in the annealed (O) and solution heat treated (W) tempers. In the fully heat treated temper (T) the yield strength is somewhat higher than that of duralumin (17S).

Composition—The nominal composition of this alloy is silicon 1.00%, magnesium 0.6%, and the balance aluminum, plus impurities. Iron and copper are always present in ingots used in the manufacture of this alloy.

Temper Designation—The temper of this alloy is designated by a symbol or symbols following the number used to designate the alloy composition and the letter S, which indicates that it is a wrought alloy.

Properties—Typical properties of this alloy in the various tempers are given in Tables I and II.

Table I
Typical Mechanical Properties of Aluminum-Silicon-Magnesium Alloy 51S

Temper	Tensile Strength, Psi.	Yield Strength ¹ , Psi.	Elongation, % in 2 in.	Shear Strength ² , Psi.	Brinell Hardness 10mm., 500kg.
O	16,000	6,000	30	11,000	28
W	35,000	20,000	24	24,000	64
T	48,000	40,000	14	30,000	95

¹Stress which produces a permanent set of 0.2% of the initial gage length.

²Single shear strength values from double shear tests.

Table II
Physical Properties of Wrought Aluminum-Silicon-Magnesium Alloy

	51SO	51SW
Sp.gr.	2.69	2.69
Density, lb. per cu.in.	0.097	0.097

Thermal conductivity at 100°C cgs. units.	0.50	0.40
Coefficient of thermal expansion, average, 68-212°F.	0.0000130	0.0000130
Modulus of elasticity, psi.	10,300,000	10,300,000
Endurance limit psi., 500,000,000 cycles.	6,500	10,500

Corrosion Resistance—This alloy is resistant to corrosion under most atmospheric conditions. Under severe conditions of exposure paint protection is desirable.

Workability—In the annealed temper this alloy will withstand severe drawing and forming operations. After solution heat treatment (W temper) the alloy still has good workability and withstands all but the more severe drawing or forming operations. The fully heat treated temper (T) has decreased workability but, in many applications, forming can be carried out after solution heat treatment followed by aging of the formed part to the fully heat treated condition. Aging can be accomplished with little or no distortion.

Welding—This alloy can be welded using the methods employed for other aluminum alloys. The metal in the weld is in the cast condition and the effect of heat treatment is largely removed from the metal adjacent to the weld, consequently other forms of joining such as riveting are used where the maximum strength of the heat treated alloy is required.

Heat Treatment and Aging—Solution heat treatment of all forms of this alloy is carried out by heating at 960-980°F. in a fused nitrate bath or suitable air fur-

*Aluminum Research Laboratories, Aluminum Co. of America, Cleveland.

**Technical Department, Fabricating Division, Aluminum Co. of America, Pittsburgh.

†This alloy in the fully heat treated condition is covered by U. S. Patent 1,472,739.

nace. The time at this temperature depends upon the thickness of the section. After heating, the alloy is rapidly cooled to ordinary temperature with the minimum of delay, at most a few seconds, between removal from the heating medium and immersion in the quenching medium, usually cold water. This puts the alloy in the solution heat treated (W) temper.

Precipitation heat treatment or artificial aging is accomplished by reheating for 18 hr. at 315-325°F. Other aging treatments likewise at low temperatures are possible where special requirements are to be met. This operation, performed following solution heat treatment, puts the alloy in the fully heat treated (T) temper.

Annealing—Material which has not received any solution heat treatment can be completely annealed by heating to 640-670°F. and allowing to cool normally in the air. In certain forms of products, it is sometimes necessary to hold the alloy at the annealing temperature for 1 or 2 hr. to assure full annealing.

If the above mentioned annealing treatment is used on material which has been solution heat treated, a partial softening may occur and may be sufficient for some forming operations. The material, however, will not be dead soft. For complete annealing of these alloys which are in the heat treated temper, the metal should be heated for 2 hr. at a temperature of 750-800°F. and then slowly cooled to 500°F. at a rate not exceeding 50°F. per hr. The rate of cooling below 500°F. is not important.

Forms Produced—The alloy 51S is available in the form of sheet, plate, extruded shapes, tubing, and forgings.

Properties of Aluminum-Zinc Alloys

By L. W. Kempf*

General—In the early history of aluminum, zinc was considered one of the most important of the commercial hardening elements. There is, however, at present practically no commercial use of the binary aluminum-zinc alloys. A ternary alloy containing from 10-14% zinc with 2 or 3% copper is widely used in Europe for sand castings.^{1,2} In this country, also, a somewhat similar alloy with the zinc content restricted to 10 or 11% and copper to 2 or 3% with iron about 1.5% has until quite recently been produced in considerable tonnages as sand castings.^{3,4} The latter alloy is now being gradually replaced by heat treated alloys. Wrought aluminum-copper-zinc alloys have been used to some extent and there has been within the last few years an attempt to commercialize a wrought high strength alloy containing aluminum, zinc, and magnesium.⁵ Recently there has also been some commercial exploitation for forgings of a complex alloy containing about 10% zinc (Alloy 70S). There is not, however, any large production of wrought aluminum alloys containing zinc as the chief alloying ingredient.

Because of its high solubility in solid aluminum, zinc can be added in rather high percentages before encountering excessive brittleness. High tensile strengths are attainable in both cast and wrought products at relatively high percentages of zinc. There are disadvantages to the alloys containing more than about 10% zinc which more than offset the high strength and low metal cost. Among these disadvantages are high specific gravity, low strength at elevated temperatures, relatively poor casting qualities, relatively poor resistance to corrosion and, in some wrought products, a peculiar susceptibility to intercrystalline cracking under application of stress.

Properties of Castings—The tensile properties of some chill cast aluminum-zinc alloys according to Rosenhain and Archbutt⁶ are given in Fig. 1. It will be noted that the tensile strength increases continuously to about 40,000 psi. at 30% zinc.

Fig. 1—Tensile properties of chill cast aluminum-zinc alloys.

Fig. 2—Effect of zinc on the tensile properties of aluminum (bars forged).

gravity of aluminum as rapidly as does copper, higher percentages of zinc are required to produce equivalent hardening effects, so the aluminum-zinc alloys as a class are the heaviest of the common aluminum-base alloys.

The aluminum-zinc alloys are notoriously hot short. They are also quite subject to shrinkage until the zinc content becomes rather high. On the whole, the casting properties of the binary alloys are considered relatively poor. The addition of copper markedly improves the casting characteristics as evidenced by the wide use in Europe of the casting alloy containing about 11% zinc and 3% copper.

Tensile Properties of Wrought Alloys—Fig. 2 shows the effect of zinc content on the tensile properties of aluminum in the form of forged bars. 4 in. square ingots were reduced at 700-800°F. to ¾ in. square rod from which standard ½ in.

Tensile property curves of sand castings will generally parallel the curves of Fig. 1 with slightly lower values for any specific zinc content. The elongation of sand castings approaches zero above about 15% zinc. Chill castings age harden to a marked, and sand castings to a somewhat lesser, extent on standing at room temperature. The elongation for alloys containing more than about 15% zinc becomes very low after a few months time. The tensile strength is correspondingly increased.

A curve is also included in Fig. 1 depicting the variation in specific gravity of the resulting alloys with increasing zinc contents. Although zinc does not increase the specific

*Aluminum Research Laboratories, Aluminum Co. of America, Cleveland.

dia. specimens were machined. The specimens were heated 1 hr. at 880°F., quenched in water and aged 8 days at room temperature. The uniform increase in tensile strength and decrease in elongation with increasing zinc content is typical of the variation in properties of a solid solution with variation in concentration of the solute.

Up to about 12% zinc the alloys forge with considerable ease, but above this concentration their susceptibility to hot shortness renders them quite difficult to handle under the hammer. Similar observations regarding hot working properties have been made during hot rolling of alloys containing upwards of about 10% zinc. The forged alloys also exhibit spontaneous age hardening at room temperature after cooling in the air from the forging temperature.

Stress Cracking—Wrought products of aluminum-zinc alloys containing zinc concentrations higher than about 10% are susceptible to cracking or failure under the prolonged action of stresses well below the normal tensile strength. This phenomenon was encountered in the investigations of the National Physical Laboratory⁶ on alloys with zinc contents in the neighborhood of 20%. It was found that certain alloy additions, such as manganese, markedly decrease the tendency of the alloy toward this type of failure. Stress cracking can apparently be overcome by careful selection of alloy composition and control of the manufacturing processes.

Corrosion Resistance—The corrosion resistance of the aluminum-zinc alloys is generally considered to be inferior to that of the aluminum-copper or aluminum-silicon alloys. This is probably true in the alloys of such zinc concentrations that precipitation occurs at room temperature. It has been definitely shown that such precipitation decreases the corrosion resistance but also that the inherent corrosion resistance of the solid solution is not markedly inferior to that of the aluminum-copper alloys.

Polishing of Aluminum for Metallographic Examination

E. H. Dix, Jr.,* and F. Keller*

General—The method of preparing metallographic specimens of aluminum alloys is similar to that employed for other metals, although a slightly different technique is required because aluminum alloys are relatively soft and are more readily flowed or scratched.

Full size specimens can be employed for macroscopic examination if they are not too large. Generally, it is necessary to cut small specimens of convenient size for both macroscopic and microscopic examination. These can be obtained by drilling, sawing, or shearing, but care should be taken to avoid overheating of the specimen or alteration of the structure in any manner. Before proceeding with the preparation of a specimen all oil, grease, dirt or other foreign materials should be removed.

Specimens too small to be handled conveniently during polishing should be mounted. The mounting of such specimens can be accomplished in one of several ways. For instance, with samples of sheet, a pack can be made by binding a number of pieces together by means of machine screws. In making up such a composite specimen of sheet or foil the pieces assembled in the pack are sometimes separated by fillerpieces of a similar alloy. The pack should be clamped tightly in order to minimize capillary retention and subsequent exudation of the etching solutions from crevices. Where the specimen is small or irregular in shape, it is general practice to embed the specimen in a mounting medium. The most economical and convenient method consists in placing the specimen in a ring of aluminum tubing and then filling the ring with melted sulphur. Sulphur does not chip readily during polishing, nor is it affected by the etching reagents commonly used. Other mounting materials, such as sealing wax, dental cements, and fusible alloys, also may be employed. If a suitable press is available, Bakelite and some of the transparent or semitransparent plastic materials such as Lucite, Cibacite, Resiglass or Tenite may be used. Any mounting material that may induce galvanic attack during etching or that is severely attacked by etching solutions should be avoided.

Since the objects of macroscopic and microscopic examinations are different, some variations in the polishing procedure are necessary. The following methods of preparation are recommended.

Preparation for Macroscopic Examination—Large specimens can be prepared satisfactorily for macroscopic examination by machining the surface in a lathe or shaper in accordance with the recommended practice for machining aluminum.¹ Smaller specimens are first smoothed on a sharp, medium mill file or microtome. Further preparation consists in rubbing the surface on several successively finer grades of abrasive cloth or paper, beginning with No. 180 Alloxite or a similar grade and finishing with No. 0 grade emery. The papers should be coated with a solution of paraffin in kerosene and should be backed by a piece of plate glass. This grinding should be carried out so that the cut being taken on a given paper is at right angles to that taken on the preceding paper.

Preparation for Microscopic Examination—The following procedure² is recommended for the preparation of specimens for microscopic examination:

1. A plane surface is obtained in the same manner as described for macroscopic examination.
2. The specimen is then rubbed successively on No. 0, 00, and 000 metallographic emery papers, coated with a solution of paraffin in kerosene to keep the specimen bright and prevent particles of abrasive from becoming embedded in the surface.

When a microtome³ of sufficient rigidity is available it can be used to replace operations 1 and 2 and will frequently give better results. The microtome blade should be kept well sharpened at all times and should be set to remove only a thin layer of metal in each cut.

3. The first wet polishing operation is carried out on a broadcloth pad mounted on a disc rotating at about 300 r.p.m. and using No. 600 alundum or a similar material as the abrasive. A quantity of the abrasive is placed in a flask with water

*Aluminum Research Laboratories, New Kensington, Pa.

and shaken until it is in suspension. In this way the mixture can be conveniently supplied to the pad while the specimen is being polished. The suspension should be allowed to settle as polishing progresses so that successive applications to the pad will carry progressively finer particles. The pad should finally be washed free of the coarser particles by means of a stream of water from a wash bottle and the polishing with this abrasive completed using a suspension from which all of the coarse particles have settled.

4. Final polishing is done on kitten's ear broadcloth mounted on discs rotating at about 150-200 r.p.m. The pad should be moistened with distilled water (not tap water) and a small quantity of heavy magnesium oxide worked into it with the palm of the hand; gritty particles and excess oxide are brushed off. The pad should be kept moist during the polishing operation by adding distilled water from a wash bottle as needed. The polishing should be continued until all striations from the alundum cut (operation 3) are removed; to avoid surface flow the specimen should frequently be lifted from the pad and turned through 180°. As this operation approaches completion, the pad should be washed nearly free of abrasive and the specimen held on the slowly rotating pad using a plentiful supply of water. In order to secure a really good polish, the finishing of this operation must be carried out carefully. The pressure and time required depend upon the composition and temper of the specimen being prepared.

When a satisfactory polish has been secured the specimen should be washed in a stream of warm tap water and dried by blowing the excess water from the surface. Touching or rubbing the surface on anything during or after the final polishing operation must be carefully avoided.

After polishing the specimens will retain their finish indefinitely if kept in a place where dirt from the atmosphere cannot collect on the surface. A desiccator or a sterilizer cabinet makes an excellent storage place.

There are several precautions which must be taken in order to secure satisfactory results from the wet polishing operations. For instance, there are several grades of magnesium oxide prepared specifically for metallographic use and successfully employed for polishing other metals. Many of these products, however, contain caustic and produce an etching effect on aluminum and so should not be used. It is also essential that distilled water be used in the wet polishing as tap water results in the formation of hard carbonate particles which may cause deep scratches. Finally, new polishing cloths should be boiled for several hours before being used in order to soften the fibers and, when not in use, should be kept moist with distilled water acidified with HCl.

Etching Aluminum For Metallographic Examination

By E. H. Dix, Jr.* and F. Keller*

General—Metallographic specimens are etched in order to remove flowed metal from the polished surface, and to aid, by coloring or attacking constituents and phases, in revealing the microstructure. The type of etching solution required varies with the magnification to be used in subsequent examination, as well as with the purpose for which the etching solution is being employed.

Etching for Macroscopic Examination—Etching by totally immersing the specimen in the etching reagent produces the best results for macroscopic examination; however, for large sections it is often more convenient to apply the etching reagent to the surface by means of a soft cotton swab. This latter method is satisfactory provided that the etching reagent is applied uniformly to the surface. All oil or grease should be removed from the specimen before etching, otherwise the etching action will not be uniform.

Four types of etching solution are in general use for macroscopic etches. These consist of various concentrations of (1) sodium hydroxide, (2) hydrofluoric acid, (3) mixtures of hydrofluoric and hydrochloric acid, or (4) hydrofluoric, hydrochloric, and nitric acid. The HF-HCl acid mixture (No. 7, Table I), and the HF-HCl-HNO₃ acid mixture (No. 8, Table I), give the best results. When reagent No. 7 is used the specimen should be subsequently immersed in, or swabbed with concentrated HNO₃ to remove the etching products and to improve the grain contrast. Acid mixture No. 8 requires no subsequent treatment with HNO₃.

Etching for Microscopic Examination—Six etching solutions are recommended for general use in connection with microscopic examination. These are all aqueous solutions made up by volume when acids are used and by weight in the case of sodium hydroxide. They are designated No. 1-6 in Table I.†

The most generally useful etch is that of swabbing with 0.5% hydrofluoric acid for 15 sec. This satisfactorily removes surface flow, reveals any minute particles of constituents and also offers some possibilities for the identification of constituents. The other reagents are employed for specific purposes such as definite identification or for revealing grain structure of certain alloy types.

Specimens may be etched by immersion in the solution or by swabbing with a soft absorbent cotton swab moistened with the reagent. The latter method gives uniform and satisfactory results and is especially desirable in preparing a surface for photography. It is important to control the temperature of the specimen and of the reagent, the concentration of the reagent, and the time of etching. When the immersion method is employed the specimen should not be held in the solution with tongs, since these are usually of a different alloy than the specimen and produce electrolytic effects.

The Identification of Constituents—The identification of constituents is best accomplished at a magnification of 500 diameters or higher; therefore a 4 mm. objective with a 10X ocular is generally satisfactory. The first attempt to identify constituents should be made on the unetched specimen using color and manner of occurrence as a means of differentiation. For judging color the illumination should be approximately that of daylight quality. Eastman filter No. 78A converts the light of a 5 ampere carbon arc with Eastman neutral tint filter to approximately that of daylight. Any white light is satisfactory although the bluish tints aid in the separation of different constituents.

The characteristics of the principal constituents in commercial aluminum alloys as polished and after using the etching reagents previously described are given in Table II. A systematic guide for the identification of constituents similar to the one suggested by Dix and Keith¹⁷ with additions²⁸ is given in Table III. This guide is subject to the limitations of any etching procedure; but it should prove adequate as a means of identification even though the composition of the alloy is unknown.

The etching characteristics of the various constituents were obtained from a set of standard specimens prepared from high purity aluminum (99.95%) to which only the purest alloying elements were added. In these alloys the characteristic

*Aluminum Research Laboratories, New Kensington, Pa.

†Tables I, II, and III are given at end of article.

constituents occur without the presence of others that usually arise from the impurities existing in commercial ingots and alloys. For those interested in identifying constituents in aluminum alloys such a set of standards is invaluable.

Hardeners for Aluminum

By H. O. Burrows*

Alloying elements are commonly added to aluminum in the form of rich alloys containing aluminum and relatively large amounts of the alloying elements. They are usually made in one or two ways: (1) By melting both the aluminum and the element to be alloyed and mixing them in the molten condition; or (2) by melting the aluminum first, and when it has been heated to a relatively high temperature, adding the alloying element and stirring the mixture until the alloying element has been dissolved in the aluminum.

Rich alloys, which are brittle and broken readily into small pieces to obtain the desired amount, are usually cast in large ingots. Where the rich alloys are not easily broken, it is customary to cast them in small notched ingots.

Where the cooling characteristics of the rich alloys permit, a relatively uniform composition throughout the cross section of the ingot may be obtained. For example, alloys of aluminum with about 33-54% copper (the composition of the eutectic and the compound CuAl, respectively) solidify over a relatively narrow temperature range and are usually quite uniform in composition. Some other hardeners, particularly those of the hypereutectic composition, such as nickel-rich aluminum alloys and manganese-rich aluminum alloys, tend to segregate during solidification and care must be exercised in their use.

Aluminum-Copper Hardeners—The most common copper-rich aluminum alloy is one containing approximately 50% copper and 50% aluminum. The purity of the alloy will depend upon the purity of the metals used and the care exerted to avoid contamination during the alloying operation.

Various other copper-rich aluminum alloys, such as the 60-40 and 80-20 aluminum-copper alloys, are used for making additions of aluminum and copper to zinc in the manufacture of zinc-base die castings.

Composition Limits and Properties of Standard Aluminum-Copper Hardeners

	50-50 Al-Cu		60-40 Al-Cu		80-20 Al-Cu

*Castings Division, Aluminum Co. of America, Cleveland.

Aluminum-Nickel and Aluminum-Manganese Hardeners—Since nickel in concentrations higher than 6% and manganese in concentrations higher than 2% raise the melting point of aluminum rapidly, nickel-rich aluminum alloys and manganese-rich aluminum alloys are generally made with concentrations of nickel and manganese not exceeding 10%. Occasionally a 25% nickel-rich aluminum alloy is employed.

Composition Limits and Properties of Standard Aluminum-Nickel Hardeners

Aluminum-Copper-Zinc Hardeners—For zinc-base die casting alloys in which both aluminum and copper are employed, the alloying elements are added by means of a rich alloy containing aluminum, copper, and zinc. Zinc is present in the rich alloy to lower its melting point and thus facilitate alloying with metallic zinc.

Composition Limits and Properties of Typical Aluminum-Copper-Zinc Hardener

Aluminum-Iron Hardeners—For certain types of casting alloys, the presence of about 1.25% iron is desirable as it is reported to increase the hardness and wear resistance of the alloy and decrease the tendency toward hot shortness. For these alloys, iron may be introduced into the mixture by means of an aluminum-iron alloy containing between 5 and 10% iron.

The valuable properties of aluminum-bronze have been known for many years but one of the principal problems in producing good aluminum-bronze is getting the iron into solution. It has been found that iron may be introduced uniformly into the mixture through the use of an aluminum alloy containing approximately 90% aluminum and 10% iron.

Temperature Measurements in Molten Aluminum and Its Alloys

By Kirtland Marsh*

Type of Pyrometer—A thermoelectric pyrometer provides the most satisfactory means for determining the temperature of molten aluminum. The subject of thermoelectric pyrometers has been discussed in other sections of this Handbook, so only those phases of the subject pertaining particularly to the measurement of the temperature of molten aluminum will be discussed.

Cold Junctions—Since close temperature control is desirable ($\pm 20^{\circ}\text{F.}$ in the melting operation and $\pm 10^{\circ}\text{F.}$ in the pouring operation), provision should be made for maintaining a constant cold junction temperature for all thermocouples, or means must be provided to compensate for fluctuating cold junction temperatures. This is easily accomplished and is mentioned only because it is a requirement which is too often neglected altogether, or only partially met. Fluctuation of the cold junction temperature of a base metal thermocouple will produce errors in the temperature reading of about the same magnitude as the fluctuation of the cold junction temperature.

Thermocouple Protection Tubes—Every base metal thermocouple in common use is readily attacked by molten aluminum, some to a greater extent than others, but all to a sufficient extent to warrant the use of a suitable protection tube over the thermocouple wherever practicable. A thermocouple actually measures the temperature of its hot junction, so the protection tube and the hot junction must become the same temperature as the material before a correct reading can be obtained. A protection tube over a thermocouple materially increases the time required to secure a correct temperature reading. In the case of a melting furnace, the thermocouple and protection tube can be immersed as soon as the aluminum is melted down and allowed to remain in the metal at least until it is ready to be poured, so that the 5 min. or more required for the protection tube and thermocouple to reach the temperature of the molten metal is not a handicap. However, when it is desired to measure the temperature of the metal in a pouring ladle, time is an important factor and an unprotected couple is generally preferred.

Protection tubes are made preferably of grey cast iron. They are inexpensive and more resistant to attack by molten aluminum than other alloys which have been tried such as steel, wrought iron, or heat resisting steel. Even the cast iron will not satisfactorily resist molten aluminum unless given suitable protective coatings.

Protective Coatings for Tubes—A simple and inexpensive method of preventing the molten aluminum from dissolving or alloying with the protection tube consists of applying a wash made of hydrated lime or an aluminum pigment and an equal volume of water. The wash can be easily applied by a brush, particularly if the tube is heated to a temperature under the boiling point of water ($180\text{--}200^{\circ}\text{F.}$). Another method is to dip the heated protection tube once into the wash and quickly withdraw it before the tube is sufficiently chilled to prevent the rapid drying of the wash.

If the thermocouple is for use in an open top melting pot and is suspended from a point above the pot, the above wash is very effective, but if the thermocouple is mounted in such a manner that the protection tube is subject to contact with solid objects, the wash will be easily abraded or knocked off. In such cases, a protective coating much more resistant to abrasion can be made by mixing the lime with a solution consisting of 25% by volume of commercial sodium silicate and 75% water. This wash can be applied in the same manner as the lime and water wash, but the sodium silicate content should not be allowed to increase more than a few per cent by evaporation of the water, or a spongy and less satisfactory coating will result.

Protection tubes should be recoated as often as necessary to maintain an effective coating. Before a tube is recoated, it should be carefully cleaned to remove any aluminum which may cling to it, and also any previous coating which may have become loosened. Occasionally the entire tube should be scraped clean to remove any previous coat and any loose iron oxide scale, since a thick coat of

*U. S. Aluminum Co., New Kensington, Pa.

lime or loose scale will readily crack off while the tube is being heated up in the molten metal. The lime wash is much more adherent to a new cast iron protection tube which has been exposed to atmospheric influence long enough to become rusted, than to a smooth unrusted casting. The rusting should not be allowed to progress far enough to produce a loose scale.

Thermocouple Holder—A large proportion of aluminum is melted in open-top melting pots. It is generally a simple matter to suspend a thermocouple over the pot so that it may be lowered into the metal or raised out of the way as required. A satisfactory protection tube and holder for open-pot melting furnaces are shown in Fig. 1. The holder may be suspended by means of a chain attached by screws at each end. The tube is readily removed from the holder so that replacement is simple.

Fig. 1—Protection tube and holder for thermocouple. This tube may be cast with a solid end or welded shut as indicated.

Thermocouples—The measurement of the temperature of molten aluminum in pouring ladles must be accomplished easily and quickly so that the use of a thermocouple in a heavy protection tube is out of the question. Furthermore, many thermocouples themselves are sufficiently massive to require an appreciable length of time to attain temperature equilibrium in a bath of molten aluminum.

The most common form of thermocouple consists of two wires of different chemical composition welded together at one end to form the hot junction. The temperature actually measured is the temperature of the hot junction. The correct temperature of the molten aluminum is, therefore, not obtained until the thermocouple has been in the molten metal long enough for the hot junction to reach the temperature of the molten metal. If, however, the two wires are not welded, the molten aluminum will complete the electrical circuit and the true temperature of the molten metal will be indicated in a much shorter time than in the case of a welded thermocouple made of wires of the same size or mass.

A quick reading thermocouple can be made of No. 8 B. & S. gage chromel and alumei thermocouple wires. Both wires should be insulated with asbestos to within $\frac{1}{4}$ – $\frac{1}{2}$ in. of the end, otherwise the hot junction between the two wires may be formed at the surface of the molten aluminum. With the elements insulated, the

hot junction will be at or close to the ends of the elements, so the temperature at any depth in the pouring ladle can be obtained by immersing the couple to that depth.

Thermocouple Insulations—Not all types of asbestos insulation are satisfactory. The best form is a continuous felted layer of asbestos on each wire. This can be obtained from the pyrometer manufacturers.

The felted asbestos will become brittle and rub off, but with reasonable care the wear on the asbestos insulation will about equal the erosion of the wires. If the insulation wears away faster than the wires are dissolved, the bare wire should be cut off to within $\frac{1}{4}$ in. of the insulation, so that the hot junction, formed by the molten metal, is well below the surface.

Cleaning Thermocouples—Most of the molten aluminum which may adhere to the thermocouple when it is withdrawn should be shaken off before the aluminum solidifies; otherwise the next time the couple is used a much longer time will be required to obtain a true temperature reading.

The thermocouple should never be whipped against any solid object to remove the molten aluminum, because that would break off the insulation. To remove the aluminum, move the couple rapidly in a direction parallel to its length and then suddenly stop it, in a manner similar to shaking ink from a fountain pen.

Checking Pyrometers—The best pyrometers must be checked occasionally and they should be checked or calibrated at about the same temperature for which they are used. Because of the definite freezing or arrest points of pure aluminum and its alloys, it is a simple matter to calibrate the pyrometers in an aluminum foundry, as follows:

Fill a small crucible or pouring ladle with molten pure aluminum or one of the alloys shown in Table I, and immerse the thermocouple to a depth of 6-8 in. in the molten metal. While gently stirring the molten metal with the thermocouple or a stirring rod, read the temperature as indicated by the instrument at $\frac{1}{2}$ min. intervals. The temperature will drop at a relatively uniform rate until the freezing point of the metal is reached, when the drop in temperature will cease or become much reduced until the metal is entirely solidified. The temperatures given in Table I apply only to the beginning of the arrest period or to the point at which the direction of the time-temperature curve changes. If the mass of molten metal were great enough and it were vigorously stirred there would be a period during which the temperature would not change, but in practice there is generally only a change in the slope of the time-temperature curve. Enough metal should be used, stirring should be sufficiently vigorous, and the depth of immersion of the thermocouple in the molten aluminum should be great enough so that the change in slope of the curve will be sharp and well defined, rather than gradual or rounded off. No. 12 alloy does not give as sharp a change in slope as pure aluminum or the other alloys mentioned, but can be used if no other metal is available. The temperature as indicated by the pyrometer should agree with the temperature as given in the table, at the beginning of the arrest period, but if it does not the pyrometer is in error by an amount equal to the difference between the true temperature and the temperature as indicated.

Although a pyrometer in an aluminum foundry is not ordinarily used at temperatures as low as the freezing point of aluminum, the temperature at which it is used is sufficiently close to the freezing temperature that the error will be about the same.

In order to obtain a definite arrest point, the metal in the crucible should be stirred continuously by moving the couple back and forth. A heavy protection tube cannot be used over the couple, for this would almost entirely obliterate the arrest point on the time-temperature curve. The quick reading couple can be immersed directly in the molten aluminum, and the welded couples used in protection tubes in the melting pots can be immersed in the same manner if they are first given a protective coating of lime wash. The coating should be perfectly dry before the couple is immersed, and the coating must not be rubbed off while the couple is in the metal.

Not all alloys of aluminum have a sufficiently definite arrest period during solidification to make them suitable for freezing point calibrations. Furthermore, since the arrest period occurs at different temperatures for different alloys, the

metal selected must be of known composition or the freezing temperature must be determined experimentally with a pyrometer of known accuracy. It is generally possible to secure enough new metal, either commercially pure aluminum or one of the alloys mentioned in the table, for a freezing point determination.

It is not necessary to allow the metal to completely solidify in making a freezing point determination, for with a reasonable amount of metal, the arrest period will extend over several minutes, and as soon as it is definitely reached, the couple may be withdrawn and the metal dumped out of the crucible before it becomes solid.

Table I
Freezing Points of Aluminum and Its Alloys

Al	Cu	Composition by %					Total im- max. purities	Alloy	Arrest Point, °F.
		Si	Zn, max.	Fe, max.	Mg	Mn, max.			
99.95	0.05	Pure Al	1220
99.2	0.8	Comm. pure Al	1216

86.15-85.15	0.15†	12.0-13.0	0.2	0.8	•	0.7	No. 47 not modified	1071

¹Made from pure (99.95%) aluminum.

²Made from commercially pure (99.2%) aluminum.

†Maximum.

•Trace.

If the zero setting of the instrument is properly maintained, any change in calibration would ordinarily be gradual unless due to accident, in which case the error would probably be large enough to be apparent without an actual calibration. In some large aluminum foundries, the quick reading couples for taking pouring temperatures are checked once a day. The writer recommends the calibration of all quick reading couples at least once a week, and of all others, at least once a month.

Aluminum Die Castings

By G. M. Rollason¹ and Sam Tour²

Introduction—In die casting aluminum a hydrostatic pressure, usually in the neighborhood of 400-500 psi., is applied to the molten metal to force it into and hold it in the cavity of a metallic mold or die until solidification takes place. The use of this applied pressure involves specialized equipment and results in a product rather sharply differentiated from that of any other casting process. For certain applications, where a somewhat higher cost is justified, a more massive type of die casting machine, using pressures of 2000 psi. and upwards, has been developed.

The special characteristics of die castings offer a number of economic benefits where a metallic piece or part is used in large quantities. The die casting process affords:

1. Means of producing pieces at an extremely rapid rate with uniformity of material, appearance, and dimension.
2. Reduction or total elimination of the necessity for machining operations because of dimensional accuracy, ability to cast threads and core holes.
3. Means of producing integral pieces of different kinds of metal by casting into position the studs, bushings, and inserts.
4. Production of castings with thin and light sections.
5. Parts formed by assembly of sheet metal or stampings can be produced in one die casting where the integral construction gives greater strength and rigidity at considerably lower cost per piece without the need for an expensive series of punching, forming, and drawing dies, and the necessary jigs and fixtures usually employed.
6. Smooth surfaces permitting low cost of finishing operations.
7. The accurate reproduction of engraved or ornamental designs.

The initial cost of aluminum alloy die castings is slightly more than that of other common white metal die castings. To offset this cost differential, aluminum alloy die castings offer the advantages of light weight, superior resistance to corrosion, resistance to the effect of moderately elevated temperature, much higher degree of permanency of dimension and shape, and superior electrical and thermal conductivity.

Based on these characteristics, aluminum die-castings have found commercial application in the manufacture of household utensils and appliances, including washing machines and vacuum cleaners; automobile parts, such as hydraulic brake pistons, brackets, housings, pumps, carburetor bodies, and hardware; airplane engine parts; outboard motors; portable tools; electrical equipment; cases and frames for instruments and meters; gas burners; binoculars; typewriter and business-machine parts; rubber molds.

Scope and Limitations—In designing or considering the use of die castings for a given purpose, the following general characteristics should serve as a guide, but in complicated, elaborate or doubtful cases, advantage should be taken of the experience of a die casting engineer.

Size—The principles of die design and construction used in commercial work have proven applicable to successively larger and larger pieces. Aluminum die castings have been produced weighing 19 lb. with overall dimensions 36 x 12 x 9 in. Dimensions in one direction may exceed these considerably, and castings have been made of over 40 in. in length. Castings 25 in. in length are quite common. The low limit on size of die casting depends on economy and dimensional accuracy. For very small work, stampings or screw machine products should be considered.

Section Thickness—On large aluminum die castings, metal thickness can be reduced to dimensions of 0.085-0.100 in. With sections of less than 6 in. in length or width, the metal thickness may run as low as 0.050-0.065 in. It is usually desirable in designing die castings to keep wall thickness fairly uniform or at least to avoid abrupt changes in thickness. It is also desirable to keep sections as light as possible, consistent with requirements of strength and rigidity.

Dimensional Accuracy—Commercial aluminum die castings are generally produced to tolerance limits of plus or minus 0.0015 in. per linear in. of dimensions. These limits are governed by the rules for shrinkage which are established

¹Manager, Die Casting Div., Aluminum Co. of America, Gerwood, N. J.

²Vice-Pres., Lucius Pitkin, Inc., New York.

The A.S.M. does not undertake to insure anyone utilizing information published in this article against infringement of any patent or assume any such liability, also the publication of this article does not constitute a recommendation of any patent, proprietary application, or article that may be involved.

by experience. When once the shrinkage of a particular casting has been determined by successive trial and re-working of the dies, much closer limits can be maintained on dimensions of 3 in. or more. Dimensions measured perpendicular to the parting line of a casting are maintained within limits of minus nothing plus 0.010 of an in. in the largest castings, down to minus nothing plus 0.003 of an in. on small pieces.

Die castings have been produced for special purposes in commercial quantities with limits of plus or minus 0.001 of an in. across the parting line, but such close tolerances are not general. Each individual job must be engineered with specific tolerances in mind.

Cores—The coring of required holes or cavities in a die casting, wherever possible, not only reduces machining operations, but saves metal weight and permits the beneficial chilling action of the steel cores to be exerted throughout a greater part of the casting. Slight drafts are used on the cores to permit their withdrawal without injury to core or casting.

Draft on Die Casting Cores

Approximate Dia. of Hole	Amount of Draft, per in. of Depth
Less than $\frac{1}{8}$ in.*.....	0.015-0.020 in. on dia.
$\frac{1}{8}$ -1 in.	0.010 in. on dia.
More than 1 in.....	0.010-0.030 in. on dia. (depending on size and design)

*Small holes for tapping are usually cast to root dia. of thread with standard draft added.

Standard drafts may be reduced where necessary, probably involving more frequent replacement of cores.

Alloys—The great bulk of aluminum alloys used in die castings fall into three main groups:

1. Aluminum-copper alloys.
2. Aluminum-silicon alloys.
3. Combinations of 1 and 2, that is, aluminum-copper-silicon alloys with or without further additions of nickel or other elements.

Aluminum-Copper Alloys—Copper is added to aluminum in amounts varying from 4-14% and occasionally higher. The constitution of aluminum-copper alloys is described elsewhere by Dix and Richardson in *National Metals Handbook*. The effect of increasing additions of copper is to render the resulting alloys progressively harder and less ductile. At the same time, increase in copper content lowers the melting point, increases fluidity, reduces shrinkage and thereby improves die casting properties up to the point where excessive hot shortness sets in, making it impossible to eject the casting from the die without breakage. Copper has a tendency to reduce the corrosion resistance of aluminum.

Aluminum-Silicon Alloys—Silicon is added in amounts varying from 5-13%. The effect of increasing additions of silicon to aluminum is a progressive hardening and improvement in casting properties. At the same time the corrosion resistance is maintained at a high level.

The ease of casting increases with greater additions of silicon up to the eutectic composition. The constitution of these alloys has been described by Dix and Heath³ and by Gwyer and Phillips⁴. The eutectic composition is indicated at 11.6% silicon, both with and without the presence of commercial amounts of iron. This composition is widely used in commercial practice on account of the facility with which it handles in the casting operation. Although chill casting and die casting probably displace the eutectic composition and temperature to the "modified" point (13-14% Si), results in practice are that with 13% silicon, castings may show some free silicon (with consequent decrease in ductility) at points where the chilling is, for some reason, insufficient, while with silicon from 11-12.3% free silicon is much less evident, and the casting and physical properties are entirely satisfactory.

The aluminum-silicon alloys offer, in general, resistance to corrosion which is superior to that of the alloys of which copper is a constituent. For maximum cor-

³E. H. Dix, Jr., and A. C. Heath, *Equilibrium Relations in Aluminum-Silicon and Aluminum-Iron-Silicon Alloys of High Purity*, Proc. Inst. Metals Div., A.I.M.E., 1928, v. 78, p. 164.

⁴A. G. C. Gwyer and H. W. L. Phillips, *Constitution and Structure of the Commercial Aluminum-Silicon Alloys*, J. Inst. Metals, 1926, v. 36, p. 283.

rosion resistance, zinc, tin, and particularly copper should be substantially absent or held to an absolute minimum.

Aluminum-Silicon-Copper, and Aluminum-Silicon-Copper-Nickel Alloys—While the series of aluminum-silicon alloys combine advantages in casting properties and corrosion resistance over the series of aluminum-copper, the latter are occasionally preferred for special purposes such as ease of machining and brighter color. Silicon imparts a slightly bluish tinge to the aluminum alloys. The commercial use of the aluminum-silicon-copper series, therefore, has been a natural and successful result of efforts to combine the advantages of both the preceding types. Nickel additions to aluminum die casting alloys are especially useful in brightening the color. A comparatively wide variety of analyses used in commercial practice for these alloys is largely a reflection of varying individual preferences among manufacturers and users. Some typical alloys are given in Table I.

The alloys of aluminum with one or more of the elements copper, silicon, and nickel cover all but a small percentage of present commercial alloys. Other elements such as manganese, iron, zinc, and tin, except where present in small amounts as impurities, are not usually found.

Magnesium has not hitherto been used extensively as an alloying element in aluminum die casting because the resulting alloys tend to be sluggish and are difficult to cast. Changes in die casting methods are tending to overcome this difficulty and may result in a more extensive use of this class of alloys. They offer the advantages of good physical properties and retain good color and luster after polishing.

Impurities in Aluminum Alloys—Aluminum alloy die castings are not critical to the presence of small amounts of impurities which may be present in commercial grades of primary aluminum or of the better grades of secondary aluminum, as has been shown by the extensive test program carried out by Committee B-6 of the A.S.T.M.

Secondary aluminum alloys are used extensively and quite satisfactorily in the production of commercial aluminum die castings. With the use of proper remelting conditions and adequate analytical control, scrap aluminum of suitable purity and cleanliness can be used, either with or without addition of primary aluminum, for the production of the alloys commonly called for in commercial specifications. Clean sheet clippings constitute an excellent source of secondary aluminum. Clean scrap castings of known composition may also be used to the extent that the composition corresponds or can be corrected by the addition of other metal, to that of the desired alloy. Because of the tendency of the alloys to pick up iron during the die casting process, the iron content of the alloy ingot should be held as low as commercially practicable.

Commercial die castings usually contain more than 1% of iron regardless of the original source of the metal. Iron is absorbed by the molten alloy from the melting pot and other parts of the die casting machine. The amount which may be present without harmful effect varies to some extent with the nature of the alloy. In some die casting alloys, the maximum percentage of iron is specified as 2.5%; in only one commercial alloy (No. IX, Table I) is the limit set at less than 2% (1.8%). Iron acts as a hardener in all of the alloys and when present in excessive amount, causes the alloy to be sluggish in the casting process and reduces the elongation and shock resistance of the resulting die casting.

Manganese has an effect somewhat similar to iron, but 0.75% or less in the aluminum-silicon alloys is of some slight advantage in counteracting the coarsening and embrittling effect of excessive iron. Small additions of chromium may also be made to these alloys to accomplish the same result.

Nickel is not regarded as a harmful element in those alloys containing copper.

Zinc is undesirable, producing "hot-shortness" in the casting operation, and its presence in amounts exceeding 1% indicates heavy use of low-grade aluminum scrap. Zinc is preferably kept below 0.75%.

For some applications in which the requirements are unusually exacting, it may be desirable to limit the impurities more closely than is necessary for the general run of commercial die castings.

Typical Commercial Alloys—The selection of aluminum die casting alloys for various purposes has resulted in wide variety of mixtures. Committee B-6 of the A.S.T.M. conducted a large number of physical tests on about 12 different mixtures. Eight of these alloys, as given in Table I, are quite representative of the range

Table I
Aluminum Die Casting Alloys

Alloy No.		Copper	Nominal Composition, % Silicon	Nickel	Aluminum
IV	Al-Si Series	{..	5	Balance
V		{..	12	"
VI	Al-Cu-Si Series ..	{2	3	"
VII		{4	5	"
VIII	Al-Cu-Si-Ni	{1.5	1.5	2 25	"
IX		{4	1.75	4	"
XI	Al-Cu-Si Series ..	{2	8	"
XII	Al-Cu Series	{7	1.5	"

of present commercial die casting alloys. Compositions may vary somewhat from those in the table according to particular requirements.

Alloy No. IV, V, VII, and XII, as given in Table I, are the most extensively used, but No. VI, VIII, and IX together with slight variations or combinations have certain applications.

Physical Properties—It should be thoroughly understood that mechanical properties quoted for die casting alloys are usually based on tests of special test bar specimens. Differences of several thousand psi. are found between flat test specimens $\frac{1}{2} \times \frac{1}{2}$ in. in the test section and round test specimens $\frac{1}{4}$ in. dia. in the test section. Individual specimens cut from die castings give widely different results, depending on casting thickness and manufacturing practice. The results of tension and impact tests on bars that were tested without machining, as given in Table II, are most useful as a comparison of the physical properties of different compositions in pressure-cast test pieces under identical conditions.

Table II
Physical Properties of Aluminum Die Castings¹

XII	33,000	1.0	1.5	2.85

¹Specimens pressure-cast and tested without machining.

Selection of alloy for a given die casting depends largely on the type, size, and use of the casting. In addition to casting and physical properties, consideration must often be given to such items as color, machinability, ease of plating, surface hardness, and resistance to corrosion.

Machining Aluminum Die Castings—Extensive machining operations on die castings are not usually called for and ordinarily consist of light turning, reaming or edge milling, and the tapping or milling of internal threads. External threads are usually cast with sufficient accuracy to require only light chasing. The general principles of tool design given by R. L. Templin elsewhere in A.S.M. Metals Handbook for machining aluminum are applicable to the machining of aluminum die castings.

For turning operations on aluminum-silicon alloys, tool bits or tips of the tungsten carbide materials have been found to last from ten to twenty times longer without regrinding than the best grades of high speed steel with the same feeds and slightly higher cutting speeds.

Finishing Aluminum Die Castings—For many uses the natural finish of aluminum alloys, as produced from the dies, is satisfactory. When desired, a wide choice of special finishes are available at varying costs. Commercial finishing operations are as follows:

Sand Blasting—Sand blasting can be performed in any standard equipment which is suitable to the size and quantity of the work. A fine clean sand should be used (such as No. 1½ flint) and renewed frequently to avoid discoloration. A sand blasted surface tends to show finger prints and other handling stains, which can be overcome by dipping the sand blasted die casting into a thin oil. Sand blasting forms an excellent preparation for painting, enameling, and lacquering.

Painting and Lacquering—These operations can be applied by ordinary standard methods of spraying, brushing, or paint dipping. Chemical treatment of the surface is not necessary for good paint adherence, and the only precaution to be observed is the cleaning of the surface (by sand blasting or washing with commercial cleaners). If this cleaning is not feasible, a priming coat of asphaltum-base paint may be applied directly to the surface of the casting. Anodic treatment (see below) forms an excellent base for painting on die castings to be subjected to exceptionally severe weathering or corrosive conditions, but is ordinarily not necessary.

The mechanical properties and dimensions of aluminum die castings are not adversely affected by temperatures (400-500°F.) used in ordinary Japanning operations.

Scratch Brushing—The finish commonly known as "scratch brush" or satin finish is similar in appearance to roughly etched glass. As the name implies, this finish is accomplished by a revolving wire scratch brush. Caution should be exercised to have castings thoroughly cleaned of oil or dirt. The most satisfactory scratch brush finish is obtained on castings which have been first subjected to an acid dip (See "Bright Dipping").

Bright Dipping—Bright dipping is commonly practiced to impart a dull white, somewhat satiny appearance to various fabricated forms of aluminum, including die castings. Alloys used in the latter usually contain a certain percentage of added silicon. Therefore, it is necessary after etching the castings with caustic or alkaline cleaning solution that the acid bath used for brightening the castings should consist of a mixture of hydrofluoric and nitric acids, which dissolves the silicon set free by the etch. A muriatic-nitric acid mixture is commonly used for aluminum sheets and aluminum-copper alloy castings. The hydrofluoric-nitric mixture necessitates the use of a dipping tank lined with chemically pure lead.

Failures to produce satisfactory results in bright dipping aluminum-silicon alloy die castings are sometimes attributable to attempts to use muriatic instead of hydrofluoric acid or to use the latter in a stone crock or the like, or by using acid which has become neutralized or diluted, or by using acid which has a top coating of oil accumulated by dipping improperly cleaned castings.

In handling the hydrofluoric-nitric acid mixture great care must be exercised not only for the protection of clothing but to avoid severe acid burns.

Ball Burnishing—Ball burnishing affords a highly economical means of putting a satisfactory grade of polishing on small die castings, although it is not equal to the regular emery, polish, and color-buff operations. The castings are agitated in a wood-lined barrel with a soap solution and steel balls.

Anodic Treatment and Coloring—Aluminum die castings can be anodically treated to produce an artificial film of oxide on the surface for protection against corrosion or a surface that can be dyed or painted.

Polishing—The following polishing operations impart the highest degree of mirror-like finish to die castings such as vacuum cleaner parts, domestic utensils, and ornamental work:

1. Emery—(glued rag wheel)
2. Emery—(felt wheel)
3. Buff—(stitched rag wheel)
4. Color—(built-up rag wheel)

The first emery operation may be conducted with No. 100 emery or coarser, depending on the amount of preliminary dressing of the surface necessary to remove nicks, scratches, and die checks. However, before proceeding to buff and color, the entire surface should be ground with emery of No. 150 grade or finer. On castings with plain uninterrupted surfaces, the felt wheel emery operation can frequently be omitted. Otherwise it is useful in avoiding "drag marks" due to rag

wheels catching in the edge of cored holes. A somewhat lower grade of finish can be accomplished at considerable saving in cost by eliminating the emery operations and simply buffing and coloring.

Plating of Aluminum Die Castings—Aluminum die castings can be plated with any of the common plating metals such as nickel, brass, chromium, and silver. The following procedure should be sufficient to enable any experienced plater to obtain satisfactory results:

1. Grind and buff to required finish.
2. Remove grease with an organic solvent or by dipping for a short time in a hot, mildly alkaline cleaner. A good cleaner consists of 1-3 oz. per gal. each of sodium carbonate and trisodium phosphate.
3. Rinse in clear cold water.
4. Dip in the following solution:

Nitric acid (sp.gr. 1.42).....	3 parts
Hydrofluoric acid (48-52%).....	1 part
Temperature	75-80°F.

The proper timing on this dip must be carefully determined by experiment, as it is the important step in the plating procedure. This is accomplished by plating samples at different times of dip, observing them, breaking them, and noting the adhesion. A properly dipped sample will show no flaking of the nickel from the aluminum and should polish readily to a high finish. Under-dipped samples show poor adhesion, while over-dipped ones do not polish readily to a high luster. Each alloy composition will have a dipping time most suited to it. Although the differences between alloys are slight, the dipping range for each alloy is wide. Usually the proper time of dip lies between 15 and 30 sec. Due to the wide dipping range the effect of temperature on the action of the dip is not very great, but as a rise in temperature speeds up the action of the dip, a correction in the dipping time is sometimes necessary.

5. Rinse in clear cold water.
6. Plate at 15 amps. per sq.ft. in the following nickel bath:

Single nickel salts (nickel sulphate).....	19 oz. per gal.
Magnesium sulphate	10 oz. per gal.
Ammonium chloride	2 oz. per gal.
Boric acid	2 oz. per gal.

The time of plating should be determined to give the desired corrosion resistance. A time of plating of 1 hr. is suggested, but this can be reduced later if it is found that thinner plate meets the service requirements. It is advised that racks with spring brass holders be used, such as are customary for chromium, to facilitate handling and insure a good contact. Other nickel solutions such as used on zinc may be substituted for the above.

7. Rinse in cold water and dry by means of a hot water dip.
8. Polish nickel.
9. Clean and plate with any desired metal, such as brass, chromium, bronze, or silver, using standard commercial methods for plating these metals.

Chromium Plating—Chromium can also be plated directly on aluminum die castings using the following steps:

1. Grind and buff to desired finish.
2. Remove grease by dipping a short time in a hot, mildly alkaline cleaner. Same cleaning solution as given for nickel plating.
3. Rinse in clear cold water.
4. If the aluminum surface is not white, dip in the following solution for a short time:

Nitric acid (sp.gr. 1.42).....	3 parts
Hydrofluoric acid (48-52%).....	1 part

If the surface is still not white, as is occasionally the case, the work should be briefly dipped in equal parts of concentrated nitric and sulphuric acids.

5. Rinse in clear cold water.
 6. Plate in an ordinary chromium bath. If a polished finish is desired, use the bath cold and polish the work with a good grade of chromium polishing compound. Hot chromium baths give whiter deposits which are difficult to buff.
- A 3 to 15 minute chromium plate from a cold bath may be used for work to be buffed. Hot chromium solutions are best suited for heavy deposits.

Oxidized and Colored Finishes—Oxidized and colored finishes on copper, brass, and silver plated aluminum die castings can be produced by using the same methods commonly employed in obtaining these finishes on the solid metals, or plated base metals other than aluminum. Oxidized finishes should be protected by a thin coat of lacquer.

Cold and Hot Forming Aluminum Alloys

By C. F. Nagel, Jr.,* and P. V. Faragher*

General—Aluminum and its alloys, like other metals, strain harden when worked below their annealing temperatures. The increase in the tensile strength based on the strength of the alloy in the annealed (or heat treated) temper is directly proportional to the amount of cold work expressed as the fractional reduction of the initial cross sectional area. This direct proportionality applies throughout most of the range normally used in commercial manufacturing operations. For higher reductions the tensile strength increases more rapidly than would be indicated by this relationship.

The yield strength of annealed (or heat treated) material, that is, the stress which produces a permanent set of 0.2%, is increased materially by the first small amounts of cold work, succeeding reductions producing relatively less effect, until after about 20% reduction in cross sectional area the rate of increase in this property parallels quite closely the increase in tensile strength.

The elongation decreases with increasing amounts of cold work, and, as in the case of the yield strength, the first small amount of cold work produces a relatively greater effect (in this case, a decrease) than subsequent reductions of equal amount. The first reduction of 20% usually reduces this property to about $\frac{1}{2}$ of its initial value or even less; while after a reduction of about 60%, further cold working causes little additional change in this property.

From the foregoing discussion it will be seen that the higher the tensile strength in the annealed (or heat treated) temper, the greater the amount of hardening when the metal is subjected to cold forming operations. The workability of a material cannot be judged, however, from its tensile strength alone, nor is the per cent elongation an adequate criterion. The spread between the yield strength and the ultimate tensile strength, or perhaps the ratio of these properties, has considerable bearing on the amount of cold forming which can be done without failure. Other qualities which are not determined in the tension test or by other standard methods of test, used in the inspection of metal products, also have an effect, since alloys having substantially the same physical properties may have markedly different forming characteristics.

Cold Working—The relative ease of forming the various grades and tempers, as well as the amount of forming which can be done, varies with the nature of the operation, and the type and condition of the equipment. Consequently, the trial of samples on the tools which are to be used in production finally determines the suitability of an alloy for a given application.

Ease of forming is one of the qualities of aluminum which has contributed to its widespread use. This quality is retained in varying degrees in different commercial alloys.

For drawing or stamping operations, the tools may be of cast iron, semisteel, or tool steel. For difficult jobs the condition of the surface of the die, punch, and blank holder may determine the difference between successful operation and failure. For difficult work the tools should be of tool steel and should be well polished. A slight increase in the radius around which the metal is formed may overcome difficulties experienced in forming the harder alloys on tools originally designed for more workable metals.

For most drawing operations the light lubricating oils, known as "metal oils", give excellent results. For difficult work, tallow mixed with a small amount of mineral oil is recommended.

Bending equipment and forming rolls used for other metals are used successfully to form aluminum alloys. The radius for bends, in terms of the section thickness, is usually greater for heavy sections than for thinner. The actual radius required for a given material can be determined by trial. The following table will serve as a preliminary guide in the choice of an alloy for a required bend or of the radius to be used with the aluminum alloys in common use:

*Technical Department, Fabricating Div., Aluminum Co. of America, Pittsburgh.

Approximate Radii for 90° Cold Bend of Aluminum and Aluminum Alloy Sheet

Minimum permissible radius varies with nature of forming operation, type of forming equipment, and design and condition of tools. Minimum working radius for given material or hardest alloy and temper for a given radius can be ascertained only by actual trial under contemplated conditions of fabrication.

¹Alclad 17S and Alclad 24S can be bent over slightly smaller radii than the corresponding tempers of the uncoated alloy.

§Immediately after quenching, these alloys can be formed over appreciably smaller radii.

Hot Forming—The wrought aluminum alloys are of two types: 1. Those whose various tempers are produced by definite amounts of strain hardening by cold work; and 2. those which are susceptible to heat treatment processes. The use of hot forming is more limited in the case of the first class than in that of the second.

Aluminum alloys are plastic at elevated temperatures up to a temperature range just below the melting point, within which they become brittle or "hot short".

Hot forming has a limited application among the alloys which depend upon strain hardening for their harder tempers. In the soft tempers all of them have good forming qualities; if they are heated in the harder tempers, care must be taken to avoid heating to the annealing temperature, otherwise they will be softened and will remain soft on cooling to room temperatures. Considerable improvement in the bending qualities will be gained by working at a temperature of 300-400°F., in which range there is little loss in strength and hardness on cooling to ordinary temperatures. At temperatures above 600°F. they are quite plastic, but on cooling to ordinary room temperatures they are practically in the annealed state.

In the case of the heat treatable alloys, heating may affect not only the mechanical properties but in some of the alloys may also impair their normal resistance to corrosion. Heating to 400°F. materially improves the forming qualities of the heat treatable alloys, and if held at this temperature for not more than a half hour, the loss in tensile properties does not exceed a few per cent of their normal values. In the case of 53S, 51S, and 27S, there is little change in the resistance to corrosion of the material, but in 17S and 24S this property is impaired appreciably, and particularly in the nature of the attack.

At temperatures in the heat treatment range the heat treatable alloys are quite plastic and can be severely and easily deformed. They may be reheat treated after forming or the heat may be removed by the forming dies with sufficient rapidity to constitute a quench (U. S. Patent 1,751,500), so that the properties of the heat treated tempers are developed after suitable aging. For some operations, somewhat lower forming temperatures give better results, in which case the part may be reheated to the heat treatment temperature and quenched in the die. This avoids the possibility of distortion which frequently results when the part is quenched in water. For success with this method, the dies must contain sufficient metal to provide a rapid cooling of the alloy.

Heat Treatment of Wrought Aluminum Alloys

By C. F. Nagel, Jr.,* and P. V. Faragher*

Since the articles for the individual aluminum alloys give the temperature ranges for heat treatment and the physical properties thus obtained, this article will discuss the heat treatment processes† which are actually used and the general principles involved.

General—There are several alloys of aluminum which can be wrought into desirable commercial forms and which can have their physical properties improved by heat treatment. In every case the hardening constituents in these alloys are substances whose solid solubility in aluminum is distinctly higher at elevated temperatures than at room temperatures. There are no phase changes in solid aluminum below the melting point, consequently grain refinement is not a factor in the improvement in properties. In aluminum alloys heat treatment is simply a means of more efficiently distributing the alloying ingredients so that they more effectively perform their function of hardening the metal.

Because of the complicated equilibrium relations which exist between the liquid and the solid which freezes from it, and the fact that equilibrium conditions are not maintained during the rapid freezing of commercial rolling ingots, the percentage of alloying elements varies from the center to the outside of the individual grains. An appreciable percentage of the added hardening elements is present in the form of relatively large particles of a rich alloy, or of eutectic, distributed throughout the cast ingot. These conditions persist in spite of the fact that the total amount of the hardening elements is completely soluble in solid aluminum at temperatures just below the melting point when equilibrium conditions are established.

The working of the alloy tends to break up the cast structure of the ingot and thereby increase the rate of solution of the alloying constituents when the metal is subsequently heated. In general, the heat treating temperature is made as high as possible without melting any of the eutectic material which is present in a particular alloy. At the high temperature, solution and diffusion take place to produce practically a homogeneous solid solution. The alloy is then quenched so that there is not time for the hardening elements to precipitate from solid solution during the cooling period, in accordance with their lower solubility at lower temperatures. This process is called "solution heat treatment."

On standing at ordinary temperatures the alloying constituents tend to precipitate from solid solution and to agglomerate into larger particles in accordance with their true solubility relations at room temperatures. In some of the alloys the rate of this change is so slow at room temperatures, that they must be heated slightly (around 300°F.) to increase the rate of these processes. It should be noted that the larger particles formed during "aging" or "age hardening" at room temperatures, or "artificial aging" (commonly called "precipitation heat treatment") at slightly elevated temperatures, are usually too small to be resolved by the microscope. By prolonged heating it is possible, in all cases, to cause growth to a size visible under the microscope. The size of particle which results from aging or from proper precipitation heat treatment is more effective in hardening the metal than the molecules of alloying constituents which are present in solid solution and also more effective than the larger particles which result from prolonged heating or "overaging."

The foregoing outlines the theory presented by Merica and his associates to explain the observed facts in the heat treatment of aluminum alloys. It may not completely describe the phenomena which occur, but with the slip interference theory of Jeffries and Archer, which pictures the particles as keying the crystal planes against slip, it gives a mechanical analogy which is easy to remember and explains the nomenclature in common use for these processes.

*Technical Department, Fabricating Division, Aluminum Co. of America, Pittsburgh.

†Attention is called to the fact that certain heat treatment processes and the heat treatment of certain alloys are subject to patent restrictions. The responsibility for securing the necessary authority to use the practices described rests solely with their user.

Thermal Treatment Processes—Three types of thermal treating processes are applied commonly to wrought aluminum alloys:

1. Solution heat treatment consists in heating the alloy to a temperature at which certain constituents go into solution, usually upwards of 900°F., followed by quenching to maintain constituents in solution and thus increase the mechanical properties above those of the soft or annealed temper.

2. Precipitation heat treatment, required by certain alloys, consists in heating them ordinarily after the solution heat treatment, at a moderate temperature, usually around 300°F., to reprecipitate constituents and to further increase their strength and hardness, although usually at some sacrifice in elongation. In some cases the process of fabrication leaves the alloy in a state of partial supersaturated solid solution, and the application of a precipitation heat treatment alone results in hardness and strength increases of practical importance.

3. Annealing consists in heating the alloys to remove strain hardening resulting from cold working the metal or to remove the effects of heat treatment, or both.

Thermal Treating Practice—Solution Heat Treatment Furnaces—Aluminum alloys are commonly heat treated in molten salt baths or in air furnaces. The salt bath consists either of fused sodium nitrate, or, if the bath is also to be used for annealing, a mixture of equal parts of sodium and potassium nitrates. Provision should be made for the proper circulation of the bath throughout the immersed load of metal to insure uniform temperatures in all parts of the bath. The bath in a steel or cast iron tank is heated with gas, oil burners, or electricity.

Air furnaces are usually heated electrically with the elements having low energy input per unit of radiating surface or so shielded that they do not radiate directly onto the charge. The furnace design must be such that the temperature in all parts of the working zone is within the range specified for the heat treatment of the alloy. Better results are obtained if the furnace is provided with means for air circulation. Other methods of heating which give uniform temperatures throughout the furnace are satisfactory, but less convenient in operation.

For heat treating small parts such as rivets, a small gas or oil heated pot of molten nitrate or lead is frequently used. The parts are placed in a steel tube with the bottom closed and the top covered, the tube immersed in the bath to within a short distance of the top.

Precipitation Heat Treatment Furnaces—Precipitation heat treatment is usually carried out in a furnace or oven heated electrically or by pipes containing steam under pressure. Provision for circulating the air is usually made to provide a uniform temperature throughout the furnace as well as more rapid heat transfer.

If electrical heating is used, the units should be of the type having a low energy input per unit of area. The baffles used to direct the air circulation may also serve to minimize direct radiation to the charge.

If steam is used, the temperature is readily controlled by proper regulation of the steam pressure. Except in the case of heavy stock in which minor surface action is of no consequence, furnaces in which the steam comes in contact with the charge are not used.

For small articles an oil bath serves adequately. Gas or oil fired furnaces may be used only if designed so as to permit the required temperature control.

Annealing Furnaces—Annealing furnaces are usually oil or gas fired, since the permissible temperature range for this operation is more than for the solution or precipitation heat treatment processes. Electric furnaces are also used.

Pyrometric Equipment—Since accurate temperature control is essential for best results, all pyrometers are calibrated at regular frequent intervals. Automatic temperature recorders are desirable, if not essential, to provide a record of the heating period as a means of insuring that the material has been heated for the required time at the desired temperature range and that it has not been overheated. Furnace operation is simplified by automatic temperature regulating equipment, but manual control is possible.

Solution Heat Treatment—Wrought aluminum alloys in large tonnage are heat treated successfully without difficulty. Therefore, the following detailed instructions and precautions should not be interpreted to mean that proper heat treatment of wrought alloys is a difficult process which cannot be carried out under commercial conditions. Proper practices are necessary to get satisfactory results, but with ordinary care the required methods are established readily on a normal operating basis.

The temperature of the salt bath or of the furnace should not be higher than the maximum heat treatment temperature specified for the alloy, either when the

load is inserted, or at any time during the heat treatment period. This maximum temperature is chosen as high as possible without exceeding the melting point of the eutectic which is present in the alloy. If this eutectic is melted during heat treatment, the mechanical properties and usually the surface appearance of the alloy are seriously injured.

If the alloy is not heated to the minimum temperature specified, the full mechanical properties are not developed and, in some cases, the resistance to corrosion of the resulting product is below standard.

It is not possible to obtain satisfactory results by heat treating successively different parts of a piece of metal. It must be uniformly heated throughout and quenched in all parts in the same operation.

The heating time varies with the nature of the product, the alloy, the type of furnace, the size of load and other factors. It is essential that all parts of the load be heated for a sufficient time to insure the development of the properties required for the alloy. This time of heating, after all of the load has reached the heat treatment temperature range, may be as little as 5 min. for thin gage 17S sheet (Cn 4%, Mn 0.5%, Mg 0.5%, balance Al) heated in a nitrate bath, to as much as 2 hr. for thick 24S plate (Cn 4.2%, Mn 0.5%, Mg 1.5%, balance Al), or 5-12 hr. for forgings of heavy section heated in air furnaces. This distinction between salt baths and air furnaces is made because of the slower rate of heat transfer in the latter and the element of uncertainty that all parts of the load are actually at the required temperature. The actual times required will be ascertained from experience in operating the available equipment with the types of material which are being used. The consistent development of the desired mechanical properties in the product is the criterion.

In the case of Alclad products, the minimum possible time should be used in order to avoid diffusion of the alloying constituents of the core through to the surface. Since different thicknesses of metal require different times of heating, it is preferable that Alclad products of greatly different thickness shall not be heat treated in the same load.

Quenching—After heating the alloy for the required time, it is removed and quenched. The time interval from the removal of the load from the heating bath or furnace until it is completely immersed in the quenching medium should be as short as possible, and in any event should not exceed a few seconds. Particularly in the case of thin material, the use of guard sheets will minimize the loss of heat during the period of transfer. Allowing the metal to cool in the air is equivalent to quenching from a lower heat treatment temperature, and both mechanical properties and resistance to corrosion may be impaired. Quenching in hot water or oil, or in air, may develop the required physical properties, but the resistance to corrosion is usually less than that of material quenched in cold water. Such practice may be necessary, however, in some instances to avoid warpage. Relatively slow cooling from the solution treatment may be permissible with 53S (Si 0.7%, Mg 1.25%, Cr 0.25%, balance Al) and 14S (Cn 4.4%, Si 0.8%, Mn 0.75%, Mg 0.35%, balance Al) forgings, since the resistance to corrosion of these materials does not seem to be so dependent on cooling rate as that of some of the other heat treated alloys.

If the metal has been heated in a nitrate bath, it must be thoroughly washed to remove the salt completely since otherwise it may initiate corrosion of the material. For this purpose, warm water (150°F.) may be used after the metal has been quenched in cold water, because of the greater solubility and higher rate of solution of the salt at higher temperatures.

Precipitation Heat Treatment—Some of the aluminum alloys age harden at ordinary room temperatures, others must be heated to higher temperatures to develop their maximum properties. The temperature range and time vary with the different alloys and are shown on the data sheets for the alloys.

Annealing—The annealing practice varies depending upon the condition or temper of the alloy. The strain hardening resulting from working alloys which were originally in the soft temper may be removed and the alloy completely softened by heating to a temperature in the range of 640-670°F. Heating above 670°F. causes partial solution heat treatment and consequently prevents complete softening; at temperatures below 640°F. annealing is not complete.

This same practice, applied to the alloy which has been subjected to the solution heat treatment, will remove most of the effects of heat treatment as well as

any subsequent strain hardening, so that it is suitable for all but the more severe forming operations. If, however, the heat treated alloy must be completely annealed, it must be heated for 2 hr. at 750-800°F., then slowly cooled (not faster than 50°F. per hr.) until a temperature of 500°F. has been reached. The rate of further cooling to room temperature is not important.

Nomenclature—The various wrought aluminum alloys commercially available in this country at the present time are designated by the principal manufacturer with a number followed by the letter "S" to indicate that the symbol applies to wrought material. The number may be preceded by a letter to indicate a somewhat modified composition from that of the parent alloy, for example, A17S.

The various tempers are designated by letters following the alloy symbol and separated from it by a dash, for example, A17S-T. Where more than one heat treatment is applied, the different heat treatments may be indicated by a numeral following the letter, for example, 11S-T3.

The temper resulting from complete heat treatment (including whatever aging is necessary to develop the maximum properties from heat treatment) is designated by the letter "T". The letter "W" is used only with the alloys which require precipitation heat treatment to develop their maximum properties to indicate that they have been subjected only to the solution heat treatment, for example, 53S-W. In some of these alloys there is some aging at room temperatures even though precipitation heat treatment is necessary to develop their higher properties. In these cases, the properties specified for the "W" temper are those which the material will have after a few days when this aging is practically complete. The soft temper which results from annealing is designated by the letter "O".

The alloys 17S and 24S age spontaneously at room temperatures, consequently there is no "W" temper. Immediately after quenching they are more plastic and more easily formed than after they have had time to age. (See the article in this handbook "Cold and Hot Forming of Aluminum Alloys.") Aging of these alloys, as measured by the change in physical properties, is at first quite rapid and proceeds at a gradually diminishing rate until in about four days it is practically complete.

Nitrate Hazard—Although fused nitrate baths are commonly used in the heat treatment of steel as well as aluminum, it is felt that attention may well be called here to certain dangers in their operation. Care should be taken to prevent contact of the fused salt with carbonaceous or organic material (wood, charcoal, coke, oil, or cloth) or with red hot iron or steel. Articles to be heat treated, or sludge, should not be allowed to lie on the bottom of the tank, especially if the tank is underfired, as they are apt to cause the tank to become locally overheated and be burned through. The possibility of combustible gases accumulating around the tank should be guarded against, and it is desirable to have at some distance from the tank a gas or oil shut-off valve which can be operated in emergency. Care should be taken not to put anything wet into the nitrate bath. Extra sacks of nitrate should be stored in a dry place and at a distance from the tank. Care should be exercised in adding fresh salts to the bath if at all wet; this is best done when the bath is frozen. In melting a solid bath, the salt must melt freely at the sides of the tank before melting at the bottom, to avoid generation of pressure and possible explosion. In case of a nitrate fire, avoid the use of water or of any fire extinguisher containing water. Perhaps the best fire extinguisher is dry sand, a supply of which should be kept near the tank.

Machining Aluminum and Aluminum Alloys

By R. L. Templin*

General—Aluminum and most of its commercial alloys have good machining characteristics but these characteristics differ somewhat from those of the other commonly used metals. While the tools ordinarily used for cutting steel will often give satisfactory results on aluminum and its alloys, best results will be obtained if the methods herein described are followed.

A free machining aluminum alloy is available with machining characteristics that make it better suited than the other aluminum alloys for many of the operations performed on high production machine tools.

The following instructions are divided into two parts. Part I describes recommended tools and procedure for general machine shop practice. Part II deals specifically with automatic screw machine practice.

Part I

General Machine Practice

Tool Materials—Plain high carbon tool steels perform satisfactorily in the machining of aluminum and most of its alloys, and this tool material is widely used. For quantity production work, however, high speed tool steels have replaced plain high carbon tool steels to a large extent. Tools tipped with cemented tungsten carbide show a marked improvement over both high carbon and high speed tools. Their cutting edges remain sharp much longer without regrinding and they produce a better surface finish. In fact, tungsten carbide tools are necessary for best results with aluminum alloys of a high silicon content.

Tool Shapes in General—Tools for cutting aluminum and its alloys, with the exception of the free cutting alloys, should have appreciably more top rake and side rake than those for cutting steel. Clearance is also important. In many cases the shapes are not appreciably different from those of the tools commonly used for cutting hardwoods.

Top Rake—Often the top rake is called "hook" because of the hook-like appearance it gives to the tool. It should vary from 30-50°, depending on the type of tool used, as required by the nature of the work.

Clearance—The clearance should be about 8-10°. This angle, plus the top rake angle indicated, leave about 32-52° for the total included angle of the cutting edge of the tool.

Clearance is important and must be carried around the side of the tool which advances into the work. If too small, the side of the tool will rub against the work and generate heat. If too large, the tool may tend to dig into the work and chatter.

Side Rake—A side rake of from 10-20° materially assists in the cutting action of the tool, since it tends to produce a slicing action and thus causes the tool to cut the metal more freely. Planer finishing tools have been ground with a side rake as high as 60°, in order to take full advantage of the free cutting characteristics of aluminum.

The cutting tool angles previously described apply to machining aluminum in general. While there are some tools to which these angles may not be adapted, they can be applied to many types to produce the best results. Specific values for the different angles are governed by the work to be done and the requirements of the machine in which the tool is used.

Tool Finish—In all cases it is essential that the cutting edges be keen, smooth, and free from grinding wheel scratches, burrs, or wire edges. Too much emphasis cannot be given to this requirement, because on it depends to a large extent the success of machining aluminum and its alloys. Keen edges are best obtained by finish grinding on a fine abrasive wheel, then hand stoning with a fine oilstone, or lapping, taking care that neither the angles nor the contour of the cutting edge are appreciably modified during the finishing operations.

*Chief Engineer of Tests, Aluminum Company of America, New Kensington, Pa.

Lathe Tools—Outside turning tools for use in a lathe when machining aluminum and its alloys may be of the form shown in Fig. 1, but tools of this kind, when prepared from the usual tool bit stock, require considerable grinding in order to produce the desired shape, and it is sometimes difficult to maintain the values for the different angles when regrinding. A better tool is shown in Fig. 2. The bit of this tool is made from annealed high carbon or high speed steel. Resharpener is readily accomplished by holding the bit by its shank in the chuck or collet of a tool grinding machine or lathe, and grinding off the outside diameter until a keen edge is obtained. After each grinding, the tool should be stoned as previously indicated. When using such a tool and resharpening procedure, it is comparatively easy to maintain the desired shape throughout the useful life of the tool. Also, this tool has proved more economical than those ground from square or rectangular tool bit stock, and possesses certain adjustable features. When the clamp screw of the tool bit holder is loosened, the bit may be rotated to various positions and thus be adjusted to different working conditions. Tools of this form may be used for both rough turning and finishing cuts, but where the same tool is used for both it should be restoned before using as a finishing tool. With some modifications, either of these two forms of tools may be adapted for boring operations.

Fig. 1—Lathe tool that may be used with aluminum.

Fig. 2—Lathe tool recommended for use with aluminum.

Fig. 3—Planer and shaper tool for machining aluminum.

Fig. 4—Planer tool for roughing aluminum.

These tools, like most others suitable for machining aluminum and its alloys, tend to produce continuous chips, which usually are curled only a little when the tools are functioning properly. Decreasing the top and side rake angles tends to curl the chips more and hence to break them up. The extent to which this may be done and yet obtain the desired surface finish depends largely on the particular alloy that is being machined.

Parting tools for machining aluminum should have from 12-20° top rake and should be stoned so that their cutting edges are keen and smooth. With such tools the front clearance angle should be decreased to about 5-6°.

Facing tools should be ground so as to have a side rake similar in amount to that indicated for the top rake of the outside tools.

Planer and Shaper Tools—The tool shown in Fig. 2 can be readily adapted to planer and shaper work by using a holder, as shown in Fig. 3. Here again the tool may be used for both roughing and finishing work when machining aluminum, but a side cutting tool, as shown in Fig. 4, can be used to better advantage for heavier roughing cuts.

When finishing aluminum in a planer or shaper, care must be used to prevent the tool striking or rubbing on the finished surface during the return stroke of the tool. If the tool strikes, the work may be scratched and the thin edge of the tool broken.

Milling Cutters—Milling cutters, straddle mills, end mills, and similar cutters work to best advantage in machining aluminum and its alloys if they are of the coarse tooth spiral type and have a considerable amount of top rake on their cutting edges. In some instances milling cutters with nicked teeth assist in decreasing the chip size. Face milling cutters should be designed so that the inserted teeth have appreciable top and side rake. The helical milling cutters, primarily designed for machining steel, work especially well with aluminum and its alloys if the cutting edges are provided with suitable top rake. The same may be said of staggered tooth milling cutters.

Threading Tools—Excellent threads may be chased even in the softest aluminum with an engine lathe using a single pointed threading tool having considerable top and side rake. Hand and machine taps will produce smooth and accurate threads

Fig. 5—Types of twist drills, $\frac{1}{8}$ -in. dia. From left: Single flute, 40° spiral angle; double flute or standard, 24° spiral angle; and special double flute, 47° spiral angle.

in aluminum if they are of the spiral flute, ground thread type. Experience has shown that such taps preferably should have a right-hand spiral flute when intended to cut a right-hand thread and the spiral angle should be similar to that used in an ordinary twist drill. Taps which have a short spiral ground on the front end, such as the "gun" tap or spiral pointed tap, will often work satisfactorily in aluminum when there is room for the chips to be forced ahead of the tap and when the thread to be cut is not tapered, but taps of this type are not satisfactory for taper threads or for use as bottom taps. When using spiral fluted taps, especially in automatic screw machines, it has been found advantageous to grind a top rake on the back of the lands so that there will be less tendency for the tap to tear the threads when backing out of the work.

Thread chasers for self opening die heads and collapsible taps should be ground with appreciable top and side rake. Certain makes of these tools lend themselves more readily than others to modifications of their cutting angles.

Twist Drills—Like all other cutting tools for aluminum, twist drills should have keen edges, and a copious amount of cutting compound should be used. The best drill for aluminum is one in which the flutes have a large spiral angle, that is, more twists per inch than the ordinary twist drill. Ordinary drills are suitable when the holes are not deep, and for some work the single fluted twist drills used on hardwood will work satisfactorily. Polished flutes both improve the cutting action of the drill and assist materially in chip removal.

When the hole is deep in proportion to its diameter, it may be necessary to withdraw the drill from the hole occasionally to dispose of the cuttings. A high speed and light feed are also helpful, especially for small size drills. Examples of twist drills suitable for use on aluminum and its alloys are shown in Fig. 5.

Reamers—Reamers of the spiral fluted type, such as are generally used for machining steel, produce the best results on aluminum.

Saws—Since sawing is fundamentally a cutting operation, the principles which govern the shape of machine cutting tools for aluminum should be followed, as far as practical, in the selection of saws for sawing aluminum. The front of the saw teeth should have considerable top rake or hook and generally some side rake, the latter depending upon the type of saw tooth used; a hook angle of from 10-25° is recommended. To use a saw with so much hook, the sawing machine must be provided with a positive feeding device to prevent the saw from feeding into the work too rapidly, and the work must be held firmly. For some of the rougher classes of work where it is desired to feed the work by hand, the saw teeth should have little, if any, hook, but never a negative rake.

It is important that proper clearances be provided on the sides of the teeth, otherwise the teeth will drag in the saw cut and cause the saw to overheat. Saws for cutting aluminum should have comparatively coarse teeth with curved gullets free from sharp corners and burred edges to eliminate danger of chips sticking.

Circular saws for aluminum may be operated at peripheral speeds of 10,000-15,000 f.p.m. Speeds in the neighborhood of 5,000 f.p.m. or more are recommended for band saws. To obtain high saw speeds, it is, of course, important to have a machine free from vibration, because this will cause fatigue failure of saw blades or saw teeth.

A relatively fine feed, in comparison to the peripheral speed, generally should be used to avoid large cuttings. The feed will depend largely upon the kind of work.

A cutting lubricant or coolant is necessary for some classes of work, especially when sawing large, heavy sections. Mineral base lubricating oils, thinned with kerosene, provide satisfactory lubrication when fed to the sides of the saw blade. Soluble oil cutting compounds have also been found satisfactory. In some instances, an occasional application of paraffin wax or heavy grease will provide ample lubrication.

Hand hack saw blades of the "wavy-set" type work especially well with aluminum.

Files—Files with single cut coarse teeth, having considerable top rake, or "hook", work best on aluminum and its alloys. Such files, with deeply cut curved teeth, about 10 teeth per inch, are the best general purpose files. They remove metal rapidly, without the teeth loading, and produce a smooth finish. The long angle lathe file is also excellent for filing aluminum, especially for fine work. Files of this type generally have a pitch of about 14 to 20 teeth per inch with single cut teeth, cut at an angle of about 45-55°. This side rake angle causes the files to cut freely and helps to drive the cuttings from the teeth.

Ordinary files with single cut fine teeth do not work well on aluminum, and those with double cut teeth, whether fine or coarse, are no better because the teeth load with cuttings.

Grinding Wheels—Good results are obtained with commercial silicon carbide grinding wheels. The advice of the supplier should be obtained in selecting the proper grade of each commercial make of wheel.

Once a grinding wheel has been selected, there are three variables which affect the quality of a finish, namely, wheel speed, work speed, and grinding compound. A solution of soluble cutting oil and water works well as a grinding compound. It is important that the fine grindings of aluminum be strained from the compound before re-using, in order to prevent deep scratches on the finished surface. Wheel speeds of about 6,000 f.p.m. have given good results, but both wheel and work speeds can best be set by the experienced operator according to his own good judgment.

Cutting Speeds and Feeds—Wide ranges for cutting speeds and feeds may be used in machining aluminum and its alloys. The particular values for speed and feed are usually dependent on the character of the work, the type of tool, the lubricant, and the machine on which the work is done. Generally, aluminum can be machined to best advantage by using comparatively high speeds and fine to medium feeds; usually the finer the feed, the higher the speed should be.

A considerable amount of heat may be generated with tools which produce a tightly curled chip, and this may necessitate using a slower speed to prevent overheating of the tool and work. When using the slow speeds and coarser feeds, a

heavy cutting compound is preferred; this applies particularly to tapping operations. An increase in the amount of metal removed from the stock in a given time may often be accomplished by increasing the speed rather than the feed when using the tools described.

When using heavy, coarse-feed cuts in engine lathe work, a common occurrence with aluminum, as with most other metals, is the excessive friction set up on the lathe centers because of the expansion of the metal with rise in temperature. Ball or roller bearing tail stock lathe centers assist in decreasing this trouble.

Cutting Lubricants—Some of the alloys of aluminum have been machined successfully without any lubricant or cutting compound, using tools of the form described, but in order to get the best results, some form of lubricant is desirable. Kerosene oil will often serve, but usually it works better when mixed with pure lard oil. A satisfactory mixture for general use will be obtained by using equal parts of kerosene and lard oil. For heavy cuts and slow feeds such as in roughing work or tapping, pure lard oil has been found to give satisfactory results. For milling, sawing, and drilling, the soluble cutting oils are satisfactory and more economical than the kerosene or kerosene and lard oil lubricants. A continuous and copious supply of lubricant should be fed to the tool, in order to produce the best results. Cutting compounds of paraffin oil, such as are used in machining brass, may be found unsatisfactory for machining many of the aluminum alloys.

Part II

Automatic Screw-Machine Practice

Stock—The heat treated aluminum alloy, 17S-T, (nominal composition: 4% copper, 0.5% manganese, 0.5% magnesium), has been used almost exclusively for screw machine stock, but a recently developed alloy, 11S-T3 (nominal composition: 5.5% copper, 0.5% lead, 0.5% bismuth) is supplementing it in many applications. The latter alloy is well suited because its chips are small. Both alloys have similar cutting characteristics in respect to surface speed, lubricants, and types of tools used, but the free machining alloy has greater flexibility in respect to tool angles and tool feeds.

Drills—Standard twist drills are satisfactory for shallow holes, but for deep holes it is preferable to use straight fluted drills or twist drills with less twist, which have larger flutes to provide greater chip clearance. The flutes should be polished to offer freer passage for the chips.

For deep drilling, the drill must be withdrawn from the hole for chip removal and for lubrication of the point. It is safe practice to drill to a depth of four times the drill diameter on the first entrance, one and one-half to two times the diameter on the second entrance and three-fourths to one times the diameter on the third entrance.

Form and Cut-off Tools—Form and cut-off tools need not have top rake for the free machining alloy. For the other alloy a top rake of 5° is advantageous for penetration of the material and production of a smooth finish. In all cases, a side clearance of $\frac{1}{2}^{\circ}$ will aid in producing a smooth finish. Front clearance angles are determined by the design of the screw machine and the tools, and the angles generally used in screw machine practice are satisfactory for the aluminum alloys.

The side pressure of the form cutting tool, when used without support for the work, will spring the stock and break it off if the ratio of the formed length to the smallest diameter is too great. The limit for this ratio is $2\frac{1}{4}$ for the free machining alloy and $2\frac{1}{2}$ for the other alloy.

Box Tools—Box tool holders are designed so that the tool is usually set with a clearance angle of 8° but for some roughing tools this angle may be greater. The angle of the cutting edge with respect to the tool shank should, of course, correspond to the clearance angle so that the edge of the blade is parallel to the axis of the work. The cutting edge may be ground square with the tool shank, or with a slight rake angle, for the free machining alloy. For the other alloy, a small groove or "hook" is ground just behind the cutting edge in order to make a thin cutting edge and to provide considerable rake. This makes the tool cut more freely and forms the chips into helical coils, which are guided out of the holder and away from the work. For long, heavy cuts the feeding cams may be notched to provide an interrupted feed to break the cuttings.

Threading Tools—Taps with "hook" as supplied by the maker may be used, but it is important that they be the ground thread type, with smoothly polished flutes to allow freer exit of the chips. Thread chasers should be provided with 15-25° top rake or "hook". Taps and chasers should be tapered or chamfered at least for one thread at the leading end of the tool so they will start more easily.

Surface Speed of Stock—Aluminum alloys can usually be machined using the maximum spindle speed available in all standard types of automatic screw machines, for turning, drilling, forming, and cutting off. They have been machined at 800 stock surface feet per minute, with no indication that such speed is excessive. How much this may be exceeded has not been determined. For threading and tapping operations, each type of machine has a suitable speed which is considered good practice for machining aluminum as well as all other materials. This speed is approximately one-third of that used for other operations.

Table I
Approximate Feeds for Standard Tools for Machining
the Free Machining Aluminum Alloys—11S-T3

Tool	Cut Width or Depth, in.	Dia. of Hole, in.	Feed per Revolution, in.
Box Tools One chip finishing.. . . .	$\frac{1}{16}$	0.012
	$\frac{1}{8}$	0.010
	$\frac{3}{16}$	0.008
	$\frac{1}{2}$	0.008
	$\frac{3}{4}$	0.006
Center Drills	Under $\frac{1}{8}$	0.004
	$\frac{1}{8}$ and over	0.008
Cut-off Tools Circular.....	$\frac{3}{16}$ - $\frac{1}{8}$	0.0035
	$\frac{1}{2}$ - $\frac{3}{8}$	0.003
Drills	$\frac{1}{16}$	0.004
	$\frac{1}{8}$	0.007
	$\frac{3}{16}$	0.010
	$\frac{1}{2}$	0.012
	$\frac{3}{4}$	0.014
	$\frac{1}{2}$	0.015
	$\frac{3}{4}$	0.016
	$\frac{1}{2}$	0.017
	$\frac{3}{4}$	0.017
	$\frac{1}{2}$	0.017
Form Tools	$\frac{1}{16}$ - $\frac{1}{4}$	0.002
	$\frac{3}{16}$ - $\frac{1}{2}$	0.0012-0.0015
	$\frac{5}{16}$ - $\frac{3}{4}$	0.001
	1	0.001
Reamers	{ 0.003-0.004	Under $\frac{1}{8}$	0.007-0.010
	{ 0.004-0.008	$\frac{1}{8}$ and over	0.010

The lighter weight of aluminum, about one-third that of other commonly used metals, is an advantage when using high spindle speeds. Its lower inertia causes less wear on the spindles, belts and motors, especially when quick changes in speed are involved.

Tool Feeds—Tool feeds vary with cutting conditions, as well as with requirements of tolerance and finish. The feeds shown in Table I for the free machining alloy are approximate and may have to be altered to meet different situations. In some cases, the same feeds may be used for the screw machine alloy that is not free machining, but generally they should be about 15% less.

Cutting Compounds—Cutting compounds which are used for other metals are generally suitable for the aluminum alloys. A cutting compound that produces satisfactory results consists of paraffin oil, to which 5-10% of lard oil is added.

Spinning of Aluminum

By L. J. Weber*

The forming of aluminum to useful shapes is commonly done by means of draw presses, hammering and spinning, or combinations of these methods. Spinning can be used only for shaping round and oval symmetrical articles. The equipment consists of a lathe, spinning chucks, and spinning tools. For small production the cost per piece is lower when produced by spinning than by other methods of forming.

The aluminum best suited for spinning is commercially pure aluminum in the annealed condition. Usually the shape can be spun without an intermediate anneal. If greater strength is desired in the finished article an aluminum alloy containing 1.25% manganese can be used. This alloy strain hardens more rapidly than the commercially pure aluminum, so more chucks may be necessary and on deep items an intermediate anneal may have to be used. In case annealing is necessary a fast method of heating such as immersion in a molten salt bath should be used in order to avoid grain growth. The temperature may vary between 650 and 750°F. and the time from 30 seconds to several minutes, depending on the thickness of the metal. A welding torch may be used on large items. A simple method for determining the correct temperature is to heat the metal until it will scorch a pine stick.

The drive on the lathe headstock should provide speeds of 1200, 1800, and 2400 r.p.m. The higher speeds are for spinning small items and thin sheet while the lower speed is for large items and thick sheet.

The chucks may be made of wood, cast iron or steel depending on the number of pieces to be made and the desired finish. Hardened steel chucks with a high polish produce the best surface finish.

The approximate reduction per chuck for different shaped shells is illustrated in Fig. 1. In case the items have reentrant angles a sectional chuck is necessary as otherwise it could not be removed from the spun article. Great care must be used to have the sections fit perfectly or else the offset at the joint will be impressed on the spun article.

At times the articles are such that a roll instead of a sectional chuck can be used. The roll has the contour desired in the finished shell. It is held against the aluminum to be spun by an offset spindle. This method has the advantage over the sectional chuck in that it increases production by eliminating the assembling and disassembling of the sectional chuck. It has the disadvantage that the spinning can not be done for some distance from the bottom as this is the space occupied by the back block. It also requires that the opening in the finished article be large enough to permit the entire mechanism to

Fig. 1--Reductions per spinning operation.

Fig. 2

Fig. 2--Sequence of operations for roll spinning.

*The Aluminum Cooking Utensil Co., New Kensington, Pa.

be removed readily. In order to avoid spinning to the bottom of the article, drawn shells may be formed at the bottom by bulging and the top spun to the required shape using a roll. The sequence of operations for a percolator made in this way is shown in Fig. 2.

Hickory sticks are usually used for the breakdown of the circles, then steel forming tools are used. Alloy steels intended for wear resisting applications may be used but satisfactory tools can be made from carbon steels (1.1% carbon).

Fig. 3—Hand spinning tools.

The shape of the tool depends on the shape that is to be produced as well as on the preference of the operator. A tool with a flat surface on one side and half round on the other made from $\frac{3}{4}$ in. dia. rod is suitable for most work. Such a tool is illustrated in Fig. 3.

The lubricant used for spinning may be cylinder oil, roll neck grease or soap depending on the thickness of metal and the extent to which the metal is to be deformed. Thick metal and the more complicated shapes require the heavier lubricants.

In case the spinning is done on drawn shells, care must be exercised to avoid die scratches or similar surface defects. These will act as stress raisers and in some applications may cause cracking.

The flow of aluminum during spinning is regulated in the same way as for other metals. The sequence in spinning necessary to keep the metal under control is illustrated in Fig. 4. If the flare is too large excess thinning will occur while if it is too small the shell will buckle.

Commercial production experience has shown that to produce a wall thickness of 18 gage (B. & S.) in the finished work, the original circle should be 16 gage. This amount of thinning is considerably less than is ordinarily encountered when spinning copper or brass. If the amount of reduction is much more than two gages difficulty may be encountered because of fractures. The use of several chucks aids to prevent thinning of the metal and at the same time prevents the formation of buckles.

Fig. 4—Flare on edge to keep metal under control.

Protection of Aluminum and Its Alloys Against Corrosion

By W. L. Fink*

There is a widespread belief that aluminum and its alloys need no protection against corrosion. There are, however, conditions under which protection is necessary to maintain a satisfactory appearance and to preserve the metal. The conditions under which it is necessary to protect aluminum come under two general classifications—those which damage or prevent the formation and repair of the protective oxide coating, and those conditions which set up electrolytic cells.

Aluminum is inherently a very reactive metal, and it is resistant to corrosion only because it is protected by a very thin oxide film which forms spontaneously in air. Obviously, erosion or abrasion which constantly removes this protective surface film and exposes underlying reactive metal, will greatly accelerate corrosion. (This is not to be confused with periodic cleaning, which is beneficial.) Moreover, solutions which are sufficiently acid or alkaline either dissolve the film or weaken it to such an extent that corrosion occurs. Also, environments free from water and/or oxygen prevent the formation and repair of oxide coatings and thus accelerate the attack.

Since aluminum is anodic to most other metals, the aluminum will suffer electrolytic attack if it is exposed to an electrolyte while in contact with heavy metals such as copper, tin, and lead, which are cathodic to aluminum. A similar condition develops when salts of such heavy metals are in the solution contacting the aluminum. The metallic ions are reduced to the metal by the aluminum at certain points over the surface, thus forming minute electrolytic cells which may result in relatively deep pits. Appreciably less than one part per million of copper or tin in the solution will thus greatly accelerate the pitting of aluminum.

Electrolytic cells can also be set up by variations in the concentration of the solutions in contact with the metal. For example, a layer of dirt, thermal insulation, or similar absorbent material will hold solutions in contact with the aluminum and, at areas of good contact, will shield the aluminum from oxygen. The areas thus shielded will be anodic to the adjacent surfaces and will corrode electrolytically. Crevices in joints will give rise to similar cells.

Design and Maintenance—The most elementary way to protect aluminum is to avoid the causes of corrosion which have just been mentioned or to minimize their effect by careful design and use. Designs which avoid contacts between dissimilar metals, insure adequate drainage and ventilation, and facilitate inspection and cleaning, will aid greatly in minimizing corrosive attack. Dissimilar metals can be insulated and the crevices sealed with nonhygroscopic insulation. Sisalkraft paper, rubber, synthetic rubber, and fabrics impregnated with synthetic resin varnish or marine glue are suitable for such use. Contamination by harmful heavy metal salts can often be avoided by making, storing, and transporting the material in aluminum, or in suitably painted or enameled containers.

Periodic cleaning will destroy the electrolytic cells caused by dirt or reduced heavy metals. The type of cleaner to be used varies with the conditions. For removing heavy metals, an abrasive cleaner such as steel wool, is satisfactory. For removing dirt and maintaining the appearance of architectural parts, a liquid wax is a satisfactory cleaner. A thin layer of wax is left on the surface which facilitates subsequent cleaning. Uninhibited alkaline cleaners should be avoided or used with caution, because they attack aluminum.

Solutions which attack aluminum because they are too alkaline, too acid, or contain chlorides and heavy metal salts, can frequently be inhibited by the addition of small amounts of sodium silicate, sodium chromate or certain colloids. Alkaline cleaners containing sodium carbonate or trisodium phosphate, can usually be inhibited by the use of N or GC grades† of sodium silicate. Corrosion by water which is recirculated as in air conditioning systems and which has picked up acid (CO_2 and SO_2) and heavy metals, can be inhibited by the addition of sodium chromate. The addition of a little water to anhydrous organic liquids will frequently greatly reduce the rate of reaction.

*Aluminum Research Laboratories, Aluminum Co. of America, New Kensington, Pa.
†Philadelphia Quartz Co., designations.

It is often possible to eliminate local electrolytic cells and make the entire surface equipotential by making the aluminum parts cathodic either by applying an external current or by connecting the aluminum to a more anodic metal, such as zinc. This is the procedure which has long been followed to prevent the corrosion of steel boat hulls adjacent to bronze propellers and fittings and to protect pipe lines.

When care in design and use is inadequate or is too expensive, and where the use of inhibitors is impossible, the aluminum alloys may be protected from the corroding media by suitable coatings. These coatings will be considered under three headings: Oxide coatings, metallic coatings and paint coatings.

Oxide Coatings—Since it is the natural oxide film on aluminum which makes it corrosion resistant, a method of securing better protection is to improve the oxide film. This can be done by boiling aluminum and its alloys in certain chemicals such as solutions of chromates and carbonates. The processes of this type known as Alrok* produce oxide films affording substantial protection.

More protective oxide coatings can be formed on aluminum by making the article the anode in a suitable electrolyte such as sulphuric acid, chromic acid, or oxalic acid. The coatings used to the greatest extent in this country, England, and Germany are described in references 1, 2, and 3.

Both the chemically produced and the anodically produced oxide film can be improved by after treatments known as sealing.¹ Dichromate solutions are among the most effective sealing solutions for enhancing the resistance to corrosion.

Although substantial protection is afforded by the oxide coatings in many environments, they do not afford perfect protection against all corrosive environments. A collection of dirt on an anodically coated surface exposed to an industrial or sea coast atmosphere will cause local break down of the coatings and pitting of the metal. In order to maintain an excellent appearance, it is therefore necessary to keep the surfaces clean. A liquid wax (such as Johnson's liquid wax) is one of the most satisfactory cleaners for this purpose. The film of wax left from one cleaning facilitates the next.

Metallic Coatings—Metallic coatings can be divided into two classes: those which are anodic to the aluminum alloy on which they are applied, and those which are cathodic. The protection afforded by the latter is purely mechanical. As soon as the coating is perforated at any point, the coating actually accelerates the corrosion of the exposed base metal by electrochemical action. On the other hand, coatings which are anodic to the base metal afford electrolytic protection after the coating is perforated. For this reason, coatings which are anodic are much more protective under severe corrosive conditions.

The most satisfactory of the metallic coatings are aluminum or aluminum alloys which are anodic to the base metal and fabricated integrally with it. The best known of these alloys are Alclad* 17S-T* and Alclad 24S-T. The outstanding protection afforded is illustrated by the fact that 14 gage (0.064 in.) tensile specimens of Alclad 17S-T have been exposed for 8 years to the continuous spray of the 20% sodium chloride solution at room temperature without suffering any measurable loss in tensile strength.

On rolled shapes, castings, and assemblies which can not readily be made as clad products, aluminum, aluminum alloys, zinc and cadmium may be applied in the form of a sprayed coating.² There are on the market several guns for applying such coatings. Careful preparation of the surface, as by grit blasting, is necessary in order to obtain satisfactory adherence of the coating. Moreover, sprayed coatings are porous so that it is necessary that the alloy used in the coating be anodic to the underlying metal. However, when the coating metal is suitably selected and properly applied, excellent protection is afforded. Sprayed coatings of aluminum have completely protected aluminum-copper and aluminum-silicon cast alloys against a 20% salt spray for 4 years.

Metallic coatings can also be applied to aluminum by electroplating.¹ Nickel and chromium have been used extensively and offer adequate protection if conditions are not too severe. However, both of these metals are cathodic to aluminum and, therefore, do not offer the electrolytic protection against corrosion which is afforded by zinc or cadmium.

*Registered Trade Mark, Aluminum Co. of America.

Paint Coatings—The most widely used coatings are paint coatings.¹ For best results, the surface of the aluminum should be given a suitable preparation for painting, an inhibitive primer should be used, and the top coats should be highly impermeable to moisture.

The best surface treatments are those which render the surface passive or chemically inert. Of these, the anodic coating is outstanding. It is widely used for aircraft parts² where section thicknesses are relatively small and low factors of safety are used so that little corrosion can be tolerated. Oxide coatings formed by the chemical dip method also furnish good surfaces for painting. Another good method for preparing the surface is the use of phosphoric acid solutions. There are a number available on the market.

The best inhibitive primers are zinc chromate primers such as those covered by the Navy Aeronautical specifications P27b. The zinc chromate in the primer acts as a corrosion inhibitor which maintains the passivity of the aluminum surface and prevents reaction with water or solutions which diffuse through the paint film.

An excellent paint for the top coats is aluminum paint made with a synthetic resin vehicle. This paint is highly impervious, and the metallic film which is formed by leafing of the aluminum bronze powder protects the vehicle from ultra-violet light, thus prolonging its useful life.

The above painting procedure is recommended for severe corrosive conditions. For less severe exposures a variety of materials are satisfactory.¹ Aluminum paint or other specially designed primers may be used. Primers containing lead compounds should not be used on aluminum. Some of the finishing coats may be oil base paints, long oil varnish enamels, and pyroxylin lacquers. It is important with the pyroxylin lacquers to select a primer which is compatible with the finishing coats.

Many of the processes described in the above article are covered by United States letters Patent.

Low Melting Alloys

By Kent R. Van Horn*

General—The expression "low melting metal" is generally applied to alloys having a melting point or solidification range below the melting point of pure tin, 449°F. (231.9°C.). The low melting or fusible alloys usually consist of binary, ternary, and quaternary mixtures of bismuth, cadmium, lead, tin, and in some instances a quintary alloy with mercury.

Since Charpy's¹ constitutional studies in 1898, the metals of the low melting group (bismuth, cadmium, lead, and tin) have been thought to form simple eutectiferous systems, that is, the presence of intermetallic compounds or solid solutions was not observed. Recently, limited solid solubilities have been discovered in some of the binary systems which, however, would not affect the commercial applications of the alloys.

Metallic alloys which are completely molten at temperatures appreciably lower than the melting points of the component metals have long been recognized. It is known that a binary eutectic has a lower melting point than either of the constituent elements, and that the further addition of one or more low melting metals may form a ternary or polynary eutectic with a still lower melting point.

A striking example of the lowering of the melting point of the component metals is illustrated by the bismuth-lead system. Bismuth melts at 519.8°F. (271°C.), lead at 621°F. (327.5°C.), and the resulting eutectic at 255.2°F. (124°C.). The six binary eutectic temperatures of the low melting metals range from the Bi-Pb eutectic at 255.2°F. (124°C.) to the Cd-Pb eutectic at 478.4°F. (248°C.). The addition of a third component, either cadmium or tin to the binary Bi-Pb eutectic decreases the melting point to the ternary Bi-Cd-Pb eutectic at 196.7°F. (91.5°C.) or the Bi-Pb-Sn eutectic at 204.8°F. (96°C.). Parravano² with the aid of three-dimensional diagrams established the composition of the quaternary eutectic to be bismuth 49.5, lead 27.27, tin 13.13, and cadmium 10.10%, melting at 158°F. (70°C.). Budgen³, with apparently sensitive thermal equipment, determined the freezing point of this eutectic to be 149.9°F. (65.5°C.). Consequently, 149.9°F. was generally considered to be the lowest temperature at which the quaternary mixture of the fusible metals remains molten. Recently, Thompson⁴ and Smith and Walker⁵ confirmed Parravano's value of the freezing point (which was selected for the accompanying compilation). The melting points, however, of the low melting alloys can be lowered even to room temperature by the further addition of mercury. The introduction of 16% mercury to mixtures approximating the quaternary eutectic, that is, Wood's and Lichtenberg's alloys, decreases the temperature of complete solidification to 131°F. (55°C.). Low melting alloys can be obtained in a pasty condition at room temperature by the addition of about 50% mercury.

Composition and Melting Points—Table I is a list of the low melting alloys of commercial purity. Alloys prepared from high purity metals would, of course, have a higher melting point or range. The temperatures of the melting points were obtained from the literature references included in this article, and may be subject to inaccuracies. A number of the alloys were thought to possess definite melting points at the time of publication, but have later been proved to soften and gradually liquefy over a solidification range which may or may not be appreciable. The temperature of the melting range, when present, would be useful, but authentic data are not yet available. Smith and Walker⁵ are methodically procuring this information. Also the determination of the temperature of a eutectic, having a sharp melting point under equilibrium conditions, may be subject to under-cooling phenomena and consequent variable results.

Uses of Low Melting Alloys—Low melting alloys have a wide variety of practical applications. Perhaps the chief use is in soldering operations where the lead-tin alloys constitute the majority of the soft solders employed. Improved solders are also obtained by the replacement of tin by small quantities of cadmium. Bismuth is sometimes partially substituted for tin, which produces a soft solder that has the capacity to wet copper and brass. Rose's and Newton's mixtures are alloys of the bismuth-lead-tin class used as soft solder in the pewter trade. An extraordinary solder application is due to the ability of certain fusible alloys, especially Wood's,¹⁷

to wet glass. The glass is not affected in making seals and connections in glass apparatus, because the alloys melt at low temperatures.

Low melting alloys are employed in the manufacture of safety devices for fire extinguishers and sometimes in boiler and electrical installations. The melting of the fusible alloy head in a sprinkler causes the release of water pressure and the operation of the alarm system. Different low melting alloys can be selected, depending on the desired operating temperatures.

A number of the low melting alloys have excellent casting characteristics. Lipowitz's, Wood's and other alloys approaching the composition of the quaternary eutectic are used for castings, statuettes, and dental work. Lead-tin antimony, lead-zinc and lead-tin-bismuth alloys are employed for making foundry patterns. The Pb-Sn-Bi eutectic expands on cooling and is used for taking impressions that necessitate a faithful reproduction of the finest details. The expansion of the mixture is characteristic of other alloys containing over 50% bismuth metal, which, in the pure state, expands 3.42% on freezing. The addition of mercury to a ternary or quaternary alloy lowers the freezing range sufficiently to permit the reproduction of anatomical and botanical specimens such as leaves and flowers. The classical magic spoons which melt in warm water are examples of fusible alloys to which mercury has been added.

During the war, gasoline tanks¹⁸ of a complicated design were made by the electrodeposition of copper plate on a low melting alloy casting, which was subsequently removed by immersing in boiling water.

Low melting alloys such as Wood's and Lipowitz's are frequently used for mounting small or irregular specimens in physical testing and metallographic laboratories. The casting and removal of the low melting alloy at temperatures approximating 158°F. (70°C.) will not generally impair the final result.

Recently, antimony has been substituted for cadmium to obtain a higher strength in a mixture (Matrix Alloy) approximating the quaternary eutectic ratio of the low melting metals. Matrix Alloy is frequently employed to locate dies in die shoes, guide pins in die plates and punches in punch plates.

Constant temperature baths of low melting alloys are used in quenching, drawing, and annealing operations in the heat treatment of steel and nonferrous metals. A number of alloys with various solidification temperatures are now at the disposal of the metallurgist.

Constitution of the Cadmium-Nickel Alloys

By Dr. Carl E. Swartz*

Very little information on the cadmium-nickel system is available. The diagram reproduced in Fig. 1 is a modification of the original work of Voss in 1908.

Up to 7 or 8% nickel, cadmium and nickel are completely miscible when in the molten condition. On cooling a eutectiferous system between cadmium and the intermetallic compound NiCd_7 is found to exist. This compound decomposes at 490°C . into a cadmium-rich liquid and a second intermetallic compound (of unknown composition) richer in nickel than NiCd_7 . The eutectic between cadmium and NiCd_7 is located at 0.25% nickel and melts at 318°C . The solid solubility of nickel in cadmium is nil. The dotted portions of the diagram have been located only approximately.

Extension of the diagram beyond the limits shown would necessitate working under pressures sufficient to suppress the vapor pressure of the cadmium existing at and above the high liquidus temperatures. It is doubtful as well whether these regions richer in nickel would be of more than academic interest because of the brittleness of the alloy.

Properties of the Cadmium-Nickel Alloys (With Special Reference to Their Use as Bearing Liners)

By Dr. Carl E. Swartz*

General—The cadmium-nickel alloys are the only binary alloys of white metal used at the present time for linings in heavy-duty sliding-type bearings. Depending upon the type of service anticipated, the composition may run from approximately ½% nickel to 3%, the balance being cadmium.

The general casting characteristics of the alloys are very good. The physical properties are satisfactory. The compression strength, hardness and ductility are considered to be rather high. With the additional advantage of high fatigue resistance and elevated melting temperature, the system offers bearing alloys which have given and are giving a good account of themselves.

Structure—The alloys consist of a matrix of cadmium and the compound NiCd, analysing 0.25% Ni. When more than 0.25% Ni is present, excess of NiCd, forms grains in the shape of cubes or skeleton cubes. These have a hardness comparable to that of the average intermetallic compound, while the matrix is soft and ductile, but tough. The microhardness numbers (Bierbaum scratch hardness) for NiCd, is 260 and the matrix 55. The antimony-tin in babbitt is 204 and the matrix 61.

Bond—The alloys are the only white metal bearing alloys in commercial use which are directly bonded to iron and steel. That is, all other alloys have a different metal or alloy forming the bond, rather than forming it directly. In fact, the alloy is being used to bond other cadmium-base alloys to steel. The type of bond

itself is also unique, in that it is a solution-type rather than the type in which an intermetallic compound is formed with the iron. The nickel soaks into the iron surface slightly, after which the cadmium alloys with the nickel. As a result of this solid solution, the bond is much more ductile than ordinarily found and consequently appears to be much stronger.

Bonding is done in the manner conventional for other white metal alloys. The steel backing material after

fluxing is dipped in the cadmium-nickel alloy. After it is heated to the bath temperature, a thin layer of the cadmium-nickel alloy is deposited on the steel surface. The steel is then removed and while hot, cadmium-nickel of the same composition is cast onto it in the required thickness.

Physical Properties—Typical values of physical properties at various temperatures are shown in Table I. The stress-strain relationship in compression is given in Fig. 1. All values in both tension and compression were obtained at a testing speed of 0.05 in. per in. of gage length. Standard specimens of 2 in. gage length and 0.505 in. dia. were used for tension tests. Compression tests were made on specimens 1 in. dia. and 2 in. long.

Although all cadmium-base bearing alloys are susceptible to corrosion at elevated temperatures when lubricated under certain conditions, this property has not proved serious in most installations.

Physical Constants of Calcium

By C. L. Mantell,* and Charles Hardy†

Introduction—In its commercial forms, calcium on freshly cut surfaces is white, approximating the color of silver. Fractured surfaces are more brilliant than steel. Upon exposure to the air, particularly in the presence of small quantities of moisture, the metal tarnishes with the formation of thin films of oxide which are bluish gray. These films are quite protective against further attack.

In contradistinction to sodium, calcium metal may be handled in a manner similar to magnesium and aluminum; that is, it may be touched and come in contact with the skin without danger. It can be machined in a lathe, turned into shapes, drilled, threaded, sawed, extruded, drawn into wire, pressed, and hammered into plates.

In its commercial forms, calcium is available as the direct product from the electric furnace, or as a remelted material, or as a sublimed material, in chips, slugs, rods, and sticks.

Atomic Weight—The atomic weight of calcium is 40.07 and its atomic number is 20. Its minimum number of isotopes is two, whose mass numbers in order of intensities of the mass spectrum lines show values of 40 and 44.¹

Crystal Form—From X-ray studies of calcium, A. W. Hull,² found that the crystals are in the cubic system with a face-centered cube lattice, with four atoms per elementary cube, a side of which is 5.56 Å and the smallest distance apart of the atoms 3.93 Å. W. L. Bragg³ gave a value of 1.70 Å for the atomic ratio.

Density—The specific gravity of calcium is 1.55. Impure material is slightly higher. According to Graf,⁴ the alpha phase in extruded calcium wire at 450°C. gives a specific gravity value of 1.48, while the beta phase at 480°C. gives a value of 1.52.

Compressibility—The compressibility or percentage change in volume with unit change in pressure of 1 megabar (0.987 atmospheres; 14,504 psi.) of calcium is given as⁵

Cubical, at 30°C., 0 atmosphere pressure.....	$\beta = 5.885 \times 10^{-6}$
Cubical, at 30°C., 11,600 atmosphere pressure.....	$\beta = 5.300 \times 10^{-6}$
Cubical, at 20°C., 99-493 atmosphere pressure.....	$\beta = 5.8 \times 10^{-6}$

$$\text{where } \beta = - \frac{1}{\text{vol. cm.}} \times \frac{dV_{\text{cc.}}}{dP_{\text{atm.}}}$$

T. W. Richards⁶ gives the average compressibility of calcium at 20°C. to be 5.7×10^{-6} between 100 and 500 megabars per sq.cm. Small amounts of carbides, chlorides, iron, and related materials increase the hardness of commercial calcium.

Thermal Expansivity—The thermal expansion of calcium is given⁷ as 0.000025 cm./cm./°C., while P. W. Bridgman⁸ found the coefficient of cubical expansion from 0-21°C. to be 0.000717. The linear coefficient of expansion of solid calcium between 0 and 300°C. is given as 220×10^{-7} .

Freezing Point—The freezing point of pure calcium is given in terms of a melting point at 810°C. W. Guertler and M. Pirani⁹ give a value of 809°C. According to recent investigations of Antropoff and Falk, the true melting point of nitride-free sublimed calcium is at a temperature of 851°C. $\pm 1^\circ$.

Specific Heat—The specific heat of calcium is 0.157 for the range from -185°-20°C., and 0.149 from 0°-100°C.

The heat of evaporation is given as 4.53×10^4 calories per mole.¹⁰

Entropy—The entropy of calcium is given by G. N. Lewis¹¹ as 10.64 for the solid and 36.71 for the vapor at 25°C. and one atmosphere pressure.

Boiling Point—The boiling point¹² of calcium is 1170°C. N. B. Pilling¹⁴ gives the following vapor pressures in millimeters of mercury, calculated from the rate of evaporation in a vacuum:

*Consulting Metallurgist, and †Pres., Hardy Metallurgical Co., New York.

At 300°C.	9.6 × 10 ⁻⁸
At 400°C.	4.2 × 10 ⁻⁸
At 500°C.	3.7 × 10 ⁻⁸
At 600°C.	1.2 × 10 ⁻⁸
At 700°C.	0.19
At 800°C.	1.8
At 900°C.	10.6
At 1000°C.	47.2

The latent heat of vaporization is 399 kilojoules per g. atom.¹¹

Thermal Conductivity—The thermal conductivity of calcium is low as compared to silver or copper, being of the same order as sodium and the alkali metals.

Electrical Resistance—In comparison with silver and copper, calcium is a poor conductor of electricity. It has an electrical resistance at 0°C. of 3.43 micro-ohms/cm.² according to J. H. Goodwin.¹² Its temperature coefficient of electrical resistance is 0.00457. In the case of metal containing 1.08% chlorine, P. H. Brace¹³ found an electrical resistance of 6.77 micro-ohms/cm.² at 22°C. The pressure coefficient of resistance of calcium increases with rising temperature, while the electrical resistance increases with rising temperature. The electrical conductivity of calcium at 20°C. is 45.1 on the basis of silver of the same area and length being taken as 100. The conductivity is exceeded only by that of silver, copper, gold, and aluminum. For the same length and weight of metal with calcium taken as 100, silver is 32.5.

Electrochemical Equivalent—Calcium occurs as a bivalent ion in all its compounds. The values in various units for the electrochemical equivalent (defined as the number of grams deposited per second by a current of one ampere) are given below.¹⁴

Mg. per coulomb	0.20762
Coulomb per mg.	4.81640
G. per ampere-hr.	0.74745
Ampere-hr. per g.	1.33789
Lb. per 1000 ampere-hr.	1.64784
Ampere-hr. per lb.	606.86

Electrolytic—According to the usual terminology, calcium is electronegative to elements it displaces in solution, and electropositive to those which displace it from solution. In simple solutions, calcium is electronegative to all of the base metals and the precious metals, and electropositive to the alkali metals. It shows an electrode potential of -2.76 volts.¹⁵

Mechanical Properties—Calcium shows a tensile strength of 8700 psi. Calcium metal is much harder than sodium, but softer than aluminum and magnesium. Its hardness characteristics are much closer to aluminum and magnesium than they are to sodium. Under 500 kg. load, sections machined out of the calcium cabbage as obtained from the furnace show a Brinell hardness of 17. Under the same conditions, sodium is so soft that measurement cannot be made, the hardness being under 1 on the Brinell scale. Pure aluminum, according to Edwards, Frary, and Jeffries,¹⁶ has a Brinell hardness of 25; while magnesium, according to the volume on magnesium published in 1923 by the American Magnesium Corporation, shows a Brinell hardness of 30, and measurements by the Dow Company on Dow magnesium show 32. On the Rockwell B scale, calcium in machined sections shows hardnesses from 36-40. On the Shore scleroscope, calcium shows hardnesses from 7-9 when the normal hammer is used, and 11-12 when the magnifying hammer is employed, as compared to values of 20-23 for magnesium.

Distilled calcium shows an elongation of 53%, while extruded wire gives 61%, 98.5% calcium 30.5%, and impure materials (94-96%) show no elongation.² The tensile strength of distilled calcium was 6,050 psi., its elastic limit 1,465 psi. With the loading speed of 4 mm. per minute, distilled calcium is more ductile than aluminum of 99.6% purity and less ductile than lead, but it has a greater elongation than both. The modulus of elasticity of distilled calcium varied between 32 × 10⁴ and 38 × 10⁴ psi. No creep was observed on loading calcium at room temperature with less than 570 psi. Crushing tests showed complete recrystallization of calcium at 300°C. and above during deformation. The pressure required for deformation decreases with the temperature and has a sharp break at 440°C., which corresponds to beta-gamma transformation temperature. Gamma calcium deforms plastically under very small loads. Calcium wire could be easily extruded between 420 and 460°C. It had an elastic limit of 5,500 psi. and a tensile strength of 8,000 psi.

Chemical Properties—Calcium at elevated temperatures oxidizes readily. This action is exceedingly rapid at its melting point, 810°C ., so that the material cannot be cast by the usual foundry methods. When melted in the absence of air, oxidizing influences, or reactive gases, it can be cast into various shapes. Recently, melting and casting procedures employing protective fluxes have been worked out for the production of cast forms of the metal from the irregularly shaped cabbages separated from the furnace electrodes.

Calcium is more active chemically than its sister metals barium and strontium. Due to its low atomic weight, 40 lb. of calcium is equivalent in reducing power to 137 lb. of barium, a ratio of more than 3:1. It is much cheaper than barium and for chemical purposes is the most economical of the alkaline earth metals.

The Copper Industry

By Wm. G. Schneider*

History—Copper, known to the Greeks as *chalkos* and to the Romans as *aes Cyprium* or metal of Cyprus, from which our name for the metal was derived, was certainly one of the first metals reduced to the service of mankind. Where it was first produced is not known. Many of the ancient peoples used it and according to Prof. Gowland,¹ the Chaldeans had developed the art of working it to a high degree as early as 4500 B.C. According to the same author, the mines of the Sinai Peninsula were systematically worked as early as 3733 B.C. and probably much before that time. Cyprus yielded copper to the Egyptians 3000 B.C. and from Egypt the use of copper and bronze spread north through Palestine into Europe.

In America copper was used by the pre-Columbian peoples and by the Indians long before the arrival of Europeans. The native metal, especially that from the Lake Superior region, was widely distributed first by the glaciers and later through trade. According to Rickard,² who has recently reviewed the matter, it is doubtful if the Indians did much, if any, mining prior to the arrival of the white man. He credits Cuba with the first mine, opened in Santiago province in 1534, and notes the discovery of copper in Massachusetts in 1632. According to Rickard, mining began at Simsbury, Conn., in 1709, and in New Jersey some time before 1719. After an abortive attempt to mine the Lake Superior deposits, made in 1771 by Alexander Henry and Alexander Baxter, these ores remained untouched until 1846 when, following the explorations of Douglas Houghton and inspired by his enthusiasm, the Cliff mine was opened.

Copper seems to have been used first for ornament, and later for tools and arms. Discovery of the hardening effect of tin produced bronze which gave various peoples in succession important advantages in war. When, where, and how brass was discovered is not known, but the early and long used method of preparation was one of direct reduction from a mixture of copper or some of its ores and calamine (zinc carbonate). It was only in 1781 that Emerson invented the process of direct fusion of the metals.

The copper, brass, and bronze industries which were well established in Roman times, passed into eclipse during the Dark Ages, but came to the front again after 900 A.D. At the time of the discovery of America the arts of manufacture were well understood and came to us from Europe. According to Rickard the manufacture of pins from native copper by Yorkshire wire drawers was started at Lynn, Mass., in 1666 by Nathaniel Robinson, and brass is reported to have been cast in the foundry of John Winthrop in the same town two years before. Both brass and copper kettles were hammered out at Philadelphia as early as 1725. By 1750 Waterbury, Conn. had an establishment where knee and shoe buckles were made, watches repaired and imported brass buttons sold. Brass sheet rolling was first done at Waterbury in 1802, since which date Connecticut has continued to be the center of American brass manufacture.³

Early American production was based mainly upon scrap and imported materials. While persistent search was made elsewhere and various small mines were opened, it was not until after the development of the Lake Superior district that an adequate domestic supply of metal became available. These mines yielded nearly 6,000,000 lb. of copper in the first decade. Following the extensive development of this region the mines of Mont., Ariz., Utah, and Nev., each in turn, became important. Other states producing smaller amounts were N. M., Cal., Tenn., Colo., Idaho, and Alaska.

Occurrence—The average copper content of igneous rocks has been estimated by F. W. Clark at 0.010%. The metal content of copper ores of the United States for 1929 averaged 1.41% copper, 0.0067 oz. of gold, and 0.262 oz. of silver per ton. The value of the gold and silver was estimated to equal 28 cents per ton of copper ore. Jullihn⁴ reviewed the development of the technology of copper production and showed how it has permitted the working of leaner ore without increasing the cost per pound of copper.

More than 95% of all copper produced is obtained from sulphide, oxide, carbonate, silicate, sulphate minerals contained in copper ores. The sulphides are by far the most important with the others following in the order given.

*The American Brass Co., New York.

Extraction and Refining—After mining, concentrating and smelting, the blister copper is electrolytically refined and then cast into commercial shapes which may have a purity of 99.95% copper. In this process, the valuable metals consisting mainly of gold and silver are recovered and impurities removed. Copper is also recovered from its ores by direct leaching, electrolytically depositing the metal from the resulting solutions, and then casting into commercial shapes, such as wire bars, ingots and ingot bars, cakes, and billets. Copper from the refinery is also available as cathode and shot. Various grades of copper are furnished such as Electrolytic, Lake (from northern Michigan) Oxygen free, Deoxidized, Phosphorized, and Casting.

Production of Copper—The figures of the American Bureau of Metal Statistics show the following production in tons of 2000 lb.:

Year	United States	World
1929	1,028,348	2,118,209
1930	710,690	1,734,745
1931	524,831	1,487,992
1932	255,509	998,103
1933	233,649	1,146,260
1934	240,099	1,395,825
1935	380,100	1,608,857
1936	614,971	1,836,480

Principal Products—Copper is used as such in the form of wire, sheet and strip, rod, tube, anodes, castings and for alloying purposes. The copper used for fabrication meets the specifications of the A.S.T.M. which require a copper content of at least 99.900% with contained silver being counted as copper. Aside from the products of copper mentioned above it is furnished in fabricated form or as castings alloyed or mixed with other metals such as zinc, tin, nickel, silicon, aluminum, manganese, iron, beryllium, cadmium, chromium, lead and others. The principal alloys obtainable in various fabricated form such as sheet or strip, pipe or tube, rod or wire, extruded shapes, are classed mainly as muntz metal, yellow brass, cartridge brass, low brass, rich low or red brass, silicon brass, commercial bronze, gliding metal, Tobin bronze, naval brass, manganese bronze, phosphor bronze, silicon bronze, aluminum bronze, nickel silver, and cupro nickel. Castings of various other compositions are also obtainable, made up of copper and the metals mentioned above.

Uses—Copper and its alloys generally speaking may be worked and fabricated by the usual metal working processes such as rolling, extruding, drawing, stamping, spinning, forging, casting and die casting. Copper or its alloys may be welded by various methods, soldered and brazed.

Copper has the highest electrical conductivity, 100%, of all of the commercial metals. On a strength basis its conductivity is more than 200% of that of aluminum. Copper is the metal used most extensively by the electrical industry where conductivity is involved.

Copper also is the best conductor of heat among the commercial metals. Because of this property it or its alloys are used for heat exchange purposes, cooking utensils, radiators and for heat dissipating equipment.

Copper and its alloys have excellent corrosion resisting qualities where exposed to all types of atmospheric and potable water conditions. Therefore, they are most suitable and extensively used in the building industry for roofing and flashings, gutters, leaders, termite shields, screening, water and drainage pipes and tubes, heating lines, hardware, lighting fixtures, windows and sash, ornamental effects, store fronts and for wires and other items too numerous to mention.

Copper and its alloys exposed to oxidizing conditions soon take on a beautiful green patina which when once formed prevents further action. The longevity of copper roofs may be attributed to the fact that the patina protects the underlying metal. Aside from atmospheric conditions copper and its alloys are used in chemical plants, underground and under many other varied conditions where because of their corrosion resisting properties the service rendered is satisfactory and economical.

Copper and its alloys have a wide range of physical properties. Tensile strengths varying from 30,000 psi. for soft copper up to 200,000 psi. for the heat

treated copper-beryllium alloy are obtainable with other physical properties fluctuating depending on alloy composition, temper, and heat treatment.

Statistics—Table I compiled by the American Bureau of Metal Statistics estimates the use of copper either as such or in the form of its alloys.

Table I
Estimated Use of Copper in the United States
(In tons of 2,000 lb.)

Constitution of Copper-Aluminum Alloys

By H. C. Jennison* and Cyril Stanley Smith†

Because of their industrial importance the constitution of the alloys of copper and aluminum rich in copper has been studied repeatedly. The work of Stockdale,¹ which is a model of accurate work by the classic methods of thermal analysis and microscopic examination of quenched samples, includes brief references to the earlier work and established the diagram for the copper-rich alloys which has not been appreciably changed by more recent work. His work forms the basis of the diagram which is shown in Fig. 1.

The liquidus slopes gradually down from the melting point of copper to a eutectic point at 8.4% aluminum where the liquid solidifies at a fixed temperature (1031°C.) to a mixture of alpha containing 7.4% and beta containing 8.8% aluminum. The liquidus and solidus are close together through the entire alpha and beta range and the alloys are therefore free from segregation on casting, an important commercial consideration. Rising from the eutectic point the liquidus reaches a flat maximum above the pure beta phase at 1048°C. and about 12.5% aluminum and then falls once more toward the region of the gamma phase.

The limit of solubility of aluminum in the alpha phase is 7.4% at 1031°C. and increases lineally to about 9.5% at 570°C. Stockdale believed the solubility limit to be 9.8% at temperatures of 530°C. and below, but the solubility 9.5% at a temperature of 570°C. is in agreement with his experimental results and it is unlikely that

Fig. 1—Copper-aluminum constitution diagram.

the solubility would continue to increase below the eutectoid temperature which is now known to be higher than he assumed. Obinata and Wassermann studied the location of the alpha boundary by X-ray methods and gave the results shown as a dotted line in Fig. 1. They state that there is no change of solubility below 650°C. and consider the solubility limit at the eutectoid point and below to be 9.43%. This is in good agreement with Stockdale's figure at 570°C. Inasmuch as X-ray studies on alloys quenched from high temperatures are somewhat uncertain (on account of partial transformation) particularly when the diffusion rate is high, it is felt that preference

should be given to Stockdale's results above the eutectoid temperature.

It should be pointed out that in other similar systems, notably the copper-tin system, when the rate of transformation has been accelerated by cold working, the solubility at low temperatures has been found to be much less than previously suspected. It is not unlikely that the same situation exists in the system at present under consideration. Obinata's and Wassermann's alloys were slowly cooled and annealed for long periods without any intermediate cold working.

The feature of greatest interest is the eutectoidal decomposition of beta which takes place at a temperature in the neighborhood of 570°C. and at a composition of 11.8-11.9% aluminum.²

The beta phase cannot be retained by quenching but gives rise to a structure bearing microscopic resemblance to martensite in steel. Although the mechanism of transformation has been studied repeatedly it is still somewhat obscure, but it can be said that there are at least three distinct transitional phases involved, each with a structure derived from one of the three equilibrium phases.⁴ It is owing to the presence of these phases that the mechanical properties of the alloys are susceptible to improvement by heat treatment.

*Deceased. †Research metallurgist, American Brass Co., Waterbury, Conn.

The recent work by Dowson⁵ indicates a greater complexity than suspected by Stockdale in the alloys from 15-17% aluminum above 963°C. On the basis of microscopic, thermal and dilatometric work, Dowson introduced the phase which, following him, is called X in Fig. 1. It decomposes eutectoidally at 963°C. to beta and gamma. This X phase is formed peritectically at 1036°C. and it gives rise to gamma by another peritectic reaction with liquid at 1022°C. Gamma itself gives rise to delta at a temperature between 780-873°C. depending on composition although these two phases are very similar to each other and no structural difference is to be found by the examination of quenched samples.

The arrangement of the gamma + delta field has been studied by Stockdale⁶ and particularly by Hisatsune.⁷ The works of Tazaki⁸ and Matsuyama⁹ are both in Japanese and difficult of access, and therefore have not been critically reviewed for this article. There seems, however, to be nothing in either diagram inconsistent with the interpretation shown in Fig. 1.

The crystal structures of the phases under consideration have been studied by a number of workers. Obinata and Wassermann¹⁰ showed that the lattice parameter of the face centered cubic alpha phase increases linearly with increasing aluminum content from 3.608 Å at 0% up to 3.658 at 19.6 atomic per cent aluminum, the limit of solubility. The beta phase¹¹ is body centered cubic with random atomic arrangement and a cube edge of 2.94 Å at 580°C. A phase beta₂ of the same lattice but with an ordered arrangement of atoms exists transitionally below the eutectoid point while the beta¹ phase which forms at lower temperatures bears some relation to alpha. The delta phase¹² has, in common with many other alloys with an electron-atom ratio of 21:13 or 1.62, the complex cubic structure typified by gamma brass. This contains 52 atoms in a unit cube of parameter increasing from 8.865-8.700 Å as the aluminum increases from 16.5-19.0 weight per cent but beyond that point (with no metallographic distinction) a slightly different structure appears in which progressively fewer atoms are associated with the unit cube, which departs slightly from true cubic symmetry and shrinks somewhat in size.

See page 1222 for a discussion of the aluminum end of this diagram.

Constitution of the Copper-Beryllium Alloys

By H. C. Jennison* and H. F. Silliman†

Lebeau^{1,2} appears to have been the first to study the alloys of beryllium and copper. He prepared a series of alloys containing up to 10% beryllium and recorded their color, malleability, tarnish resistance, and solubility in acid.

The first diagram of thermal constitution was published by Oesterheld³ in 1916. Bassett⁴ and Corson,⁵ in papers dealing with the mechanical properties of beryllium-copper alloys, later noted that the limit of alpha solubility above 650°C. is at a higher beryllium concentration than shown by Oesterheld. Corson also suggested that the solidus and liquidus over the beta field needed modification.

Masing^{6,7} and his associates redetermined the diagram in 1928 and 1929, and made several important changes in the form and position of the boundaries of the alpha and beta fields. In 1932, Borchers⁸ published a diagram which agrees closely with that of Masing except for a modification of the solidus and liquidus over the beta field.

Tanimura and Wassermann⁹ investigated the alpha field by X-ray methods and found evidence that the alpha-alpha plus beta boundary is at a slightly lower beryllium concentration than shown by either Masing or Borchers.

In the diagram here reproduced the alpha phase boundary is drawn as a mean of the results of Masing, Borchers, and Tanimura and Wassermann.

As may be seen from the diagram, the solubility of beryllium in copper increases with temperature. Alloys containing up to about 2.4% beryllium retain a pure alpha structure when quenched from a suitable temperature above the alpha boundary. In this condition the alloys are malleable and ductile, and are capable of being wrought into a variety of forms. Upon reheating such material at temperatures between 250 and 400°C. precipitation of the gamma phase occurs, bringing about a noteworthy increase in the tensile strength, elastic limit, hardness, and related properties.

The alpha plus beta alloys also show precipitation hardening effects but brittleness increases rapidly with the percentage of the beta phase in the structure so that alloys containing more than 3% beryllium cannot be cold worked.

Alloys in the beta, beta plus gamma, gamma, and gamma plus delta fields are too hard for fabrication. Castings containing 4-11% beryllium respond to heat treatments analogous to those applied to steel and may find some uses where small, extremely hard articles are required.

Of the above alloys, those containing 0.6-11.2% beryllium have an alpha plus gamma structure at temperatures below 575°C. The form and distribution of the gamma phase in the microstructure may be varied widely by reheating (below

Fig. 1—Copper-Beryllium Constitution Diagram.

Constitution of Copper-Cadmium Alloys

By Cyril Stanley Smith*

The alloys of copper and cadmium have not been subject to extensive investigation. Heycock and Neville¹ studied the molecular depression of copper on the freezing point of cadmium, and Sahmen² published a complete diagram in 1906. This showed the existence of compounds Cu_2Cd and Cu_3Cd , the first forming peritectically from copper and liquid, and the second forming directly from the liquid. Sahmen found a eutectic between these two compounds and another close to the cadmium end of the diagram between Cu_3Cd and cadmium.

In 1913 Bornemann and Wagenmann³ carried out an investigation on the electrical conductivity of the alloys in the solid and molten state and also determined the melting points and boiling points of a few of the alloys in the neighborhood of Cu_2Cd . Their results indicate unmistakably the existence of molecular association corresponding to the presence of the compound Cu_2Cd in the liquid state.

A careful examination of the equilibrium relations by Jenkins and Hanson⁴ gave the diagram shown in Fig. 1. This diagram differs from that of Sahmen principally in the introduction of a new constituent, gamma, which corresponds closely to the compound Cu_2Cd , but exists over a composition range of about 2% at 200°C. Sahmen supposed cadmium to be insoluble in solid copper, but Jenkins and Hanson introduced the alpha field, consisting of copper with a maximum of 2.7% cadmium in solid solution at all temperatures between 200°C. and the peritectic temperature, 549°C. The portion of the diagram from 45-75% cadmium is redrawn on a larger scale in Fig. 2, which shows more clearly the gamma field. The beta phase corresponds exactly to Sahmen's Cu_2Cd and has no appreciable variation in composition.

Fig. 1—Copper-cadmium constitution diagram (Jenkins and Hanson).

between 200°C. and the peritectic temperature, 549°C. The portion of the diagram from 45-75% cadmium is redrawn on a larger scale in Fig. 2, which shows more clearly the gamma field. The beta phase corresponds exactly to Sahmen's Cu_2Cd and has no appreciable variation in composition.

Fig. 2—Gamma field of copper-cadmium alloys.

The new gamma constituent of Jenkins, although the stable phase below 547°C., is not formed even with slow rates of cooling from the liquid state, but only after

Fig. 3—Alpha phase boundary in the copper-cadmium system (Owen and Pickup).

*Research Laboratory, American Brass Co., Waterbury, Conn.

long annealing at temperatures near the highest at which it is stable. Under ordinary conditions the only constituents in cast alloys within this range of composition are beta and delta, which form a metastable eutectic at a temperature of 540°C., 4°C. lower than the freezing point of the stable gamma plus delta eutectic. The molten alloys containing above 25% cadmium have a high vapor pressure, and, although no actual determinations have been recorded, the boiling point curve at atmospheric pressure evidently comes close to the liquidus at this point.

Owen and Pickup⁷ have reexamined the alloys by X-rays but were unable to determine the crystal structure of the beta, gamma and epsilon phases by the powder method used. By measurements of the parameter of samples annealed for prolonged periods at various temperatures, they established the limit of the alpha phase to be 1.2, 1.0 and 0.5% cadmium at temperatures of 500, 400, and 300°C. respectively. Their results are plotted in Fig. 3. This sloping alpha boundary is much more probable and more in keeping with the properties of the alloys than the vertical line given by Jenkins and Hanson. The work of Pogodin, Mischeva and Kagan, according to an abstract,⁸ places the alpha boundary at 1.0% cadmium at room temperature increasing to 1.2% at 250°C., 1.6% at 400°C., 2.1% at 475°C., 2.5% at 525°C., and 2.8% at 550°C. These solubilities are higher than those reported by Owen and Pickup at low temperatures. It seems likely that the lower solubility of the latter investigators is more nearly correct.

Richards and Evans⁶ studied the resistivity, temperature coefficient of resistance, thermoelectric force, Hall coefficient, density and specific heat of a complete series of alloys. The curve for each of these properties showed a discontinuity at the phase boundaries according to the diagram of Jenkins and Hanson, with which they are in complete accord. The alloys were tested in the form of cast plates which were thoroughly annealed until no further change in conductivity took place. There was little change in conductivity on annealing save with the alloys containing 56-64% cadmium where the metastable beta plus delta eutectic in castings gives rise to the stable gamma form.

The crystal structure of most of the phases is unknown. The delta phase, which is shown to range around Cu_3Cd (73.92% cadmium) rather than Cu_2Cd (72.7% cadmium), was studied by Bradley and Gregory,⁹ who found it to be cubic of the gamma brass type. There are 48 atoms in the unit cube, which has a parameter of 9.635 Å, corresponding to a density of 9.0 g. per cc. Cu_3Cd differs from Ag_3Zn , Au_3Zn , and, by analogy, from Cu_3Zn , in the division of the copper atoms among the four groups of structurally equivalent positions in the lattice. In Cu_3Cd , 16 copper atoms are divided equally by two sets of positions, only one of which is occupied by copper in Cu_3Zn , while the remaining two structurally equivalent locations, containing 12 and 24 atoms respectively, seem to be occupied indiscriminately by a group of 4 copper and 32 cadmium atoms.

Constitution of Copper-Chromium Alloys

By H. C. Jennison* and Cyril Stanley Smith†

The chromium-copper diagram has not been established with great accuracy. The commercially useful alloys contain less than 1% chromium and the only published data on this part of the system are those of Corson.¹

Studies of the complete diagram were made by Hindrichs² and Siedschlag.³ Both these investigators agree in showing a copper-rich eutectic at 1075-1076°C. and a two-liquid field existing above a monotectic horizontal at 1465-1468°C., but, whereas Hindrichs considers the two-liquid zone to extend from 1 or 2% up to more than 95% chromium, Siedschlag considers it to stretch from 37 or 38% chromium to 93% chromium. The latter figures seem to be more nearly correct. Beyond the monotectic point the liquidus rises rapidly to the melting point of chromium. The solubility of copper in chromium has not been determined, but is probably very small.

Fig. 1—Chromium-copper constitution diagram.

The melting point of the copper-rich eutectic can be stated with some certainty as being at 1076°C. The composition of the eutectic, however, is in doubt. Siedschlag stated that microscopically an alloy containing 1% chromium showed primary copper and one with 2% chromium contained primary chromium. There is no evidence to place the eutectic composition more exactly within these limits. In Fig. 1 it is arbitrarily shown as 1.5%.

The solid solubility of chromium in copper shown in Fig. 1 is that given by Corson. Without giving experimental details, he states that the solubility is 0.8% chromium at 1000°C., 0.5% at 900°C., 0.25% at 800°C., and 0.05-0.1% at 500°C. Extrapolation of the curve passing through these points indicates a solubility of about 1.25% at the 1076°C., the eutectic temperature.

There is some indication that these solubility figures are slightly high but in the absence of other determinations they must be accepted.

Constitution of Copper-Lead Alloys

By G. C. Holder*

Copper and lead in the solid state are practically insoluble. The eutectic point of this series of alloys is near the lead boundary and contains 0.06% lead. This eutectic freezes at 326°C., which is 1°C. lower than lead; freezing point being 327°C.

On the horizontal line of the liquidus at 952°C., a three phase equilibrium monotectic reaction occurs, and the two conjugate liquid solutions contain about 7.5-62% copper respectively. According to W. Claus, 1600°C. is the maximum critical point for homogeneity in accordance with results obtained by electrical conductivity; and with fall in temperature, two distinct liquid layers start forming at 999°C.

Between 100 and 62% copper, the alloys form a homogeneous solution above the liquidus curve. Temperature gradient to the liquidus causes a separation of copper crystals from the mother liquor and continues until a concentration of 62% copper is reached. Further reduction of heat causes the second liquid layer to form as copper continues to crystallize. Because of the presence of three phases, this crystallization takes place at a constant temperature of 952°C.; and when the first liquid phase is exhausted, only the second phase remains with the frozen copper. A continued temperature fall produces further separation of copper until the eutectic point at 326°C. is reached and final solidification occurs. Alloys of less than eutectic concentration have a normal freezing procedure.

Copper and lead have similar face-centered crystal structure. X-ray diffraction of copper-lead alloys show no homogeneity as the line patterns of the two base metals are compared with the alloy and show no shift in line patterns; whereas, if a compound were formed or if a solid solution were present to any appreciable degree, a shift of line patterns would be in evidence.

In an alloy containing 15% lead, fair uniformity is obtained with moderate rate of cooling. The 30% lead alloy, chilled, is also fairly uniform, but beyond 30% lead the use of fluxes; such as, manganese, arsenic, nickel, and lithium, or combination of these fluxes with temperature control, are advantageous to reduce segregation. Almost any range of hardness can be produced; as for example, an alloy of 74% lead, 20% copper, 6% nickel, together with arsenic produces an alloy that has twice the hardness of lead, good ductility, and lead sweating temperature of about 900°F. (480°C.). Sulphur is also used, but produces a brittle product.

Constitution of Copper-Manganese Alloys

By Cyril Stanley Smith*

Although Valenciennes, Heusler, Moissan, and others made and examined copper-manganese alloys as early as 1870, the first attempt to determine the constitution of the series was by E. A. Lewis,¹ who found a marked minimum in the liquidus at 47% manganese which he interpreted as indicating a eutectic between solid solutions of copper with 5% manganese, and manganese with 20% copper respectively. S. Wologdine² criticized Lewis's work and himself suggested a diagram with a minimum melting point at 40% manganese and a maximum corresponding to a compound Mn₂Cu at 78% manganese. The existence of this compound has been negated by the work of subsequent investigators, and it is probable that Wologdine's alloys absorbed carbon in amounts sufficient to give the spurious arrests he observed in his thermal curves.

In 1908 the diagrams of Sahmen³ and Zemczuzny, Urasow and Rykowski⁴ were published, both of which showed a continuous series of solid solutions, the liquidus and solidus joining at a minimum point at 35% manganese and 866°C. (Sahmen) or 30.3% manganese and 868°C. (Zemczuzny). The diagrams agreed very closely on the copper-rich side of the minimum point. There was some difference between the liquidus temperatures on the manganese side of the diagram, but the principal discrepancy between the two diagrams lay in the solidus, which Sahmen showed as practically horizontal up to 70% manganese (in approximate agreement with Lewis) while Zemczuzny showed the solidus to rise close to the liquidus. Both investigators claimed that the alloys could be rendered microscopically homogeneous, and Zemczuzny's diagram seemed more in accordance with this, and was generally accepted until very recently.

Fig. 1—Copper-Manganese Constitution Diagram.

ganese, and it became evident that the diagram needed reexamination. A diagram was then published by Ishiwara¹³ which outlined definitely the heterogeneous areas in the diagram, but later Persson and Ohman¹⁴ and Sekito¹⁵ showed that it is not impossible for copper and gamma manganese, stable at high temperatures, to be isomorphous, and Persson¹⁴ put forward the results of some X-ray determinations to prove that this was actually so.

When the constitution diagrams began to be critically examined in the light of crystal structure, it was apparent that the two metals manganese and copper, could not be isomorphous at all temperatures, for copper is face-centered cubic and the crystal structure of manganese in its low temperature modifications is far more complicated. Bain^{6,7} and Patterson⁸ found the manganese lines to appear on X-ray diffraction patterns of the alloys at 50-60% manganese, although Patterson found a change in the copper lattice even after it had presumably been rendered invariant by the appearance of manganese. Microscopic work by Corson¹² and by Smith¹³ placed the solubility limit at 800°C. at approximately 30% man-

*Research Laboratory, American Brass Co., Waterbury, Conn.

The diagram shown in Fig. 1 is slightly modified from that of Ishiwara. The liquidus is drawn as an average through the points of all investigators, as also is the solidus on the copper-rich side of the minimum melting point. The melting point and temperatures of the transformation of pure manganese are those given by Gayler,¹⁸ neglecting two points which do not seem to be accompanied by a change of crystal structure. Ishiwara placed the minimum point at about 34.5% and 850°C., but the higher temperature, 868°, has been adopted since the other investigators agree so well on this. The temperature of the gamma eutectoid is that of Ishiwara, 830°. The limit of the alpha phase drawn through Ishiwara's experimental points (confirmed by the single approximate points of Smith and Corson) intersects the liquidus and solidus at the minimum point, a condition that is thermodynamically possible only as the limiting case. Copper is soluble in the gamma form of manganese, stable between 1191°C. and the melting point, and depresses the transformation point to about 830° with 19% copper, where it decomposes by a eutectoid reaction to beta manganese and the alpha solid solution. Beta manganese later changes to alpha manganese at a temperature of about 742°. In the determination of the eutectoid temperature Ishiwara found that alloys, particularly those in the neighborhood of the eutectoid, were frequently homogeneous when they should have consisted of two phases. The reactions were extraordinarily slow and not always reproducible, rendering microscopic examination, or indeed studies of any kind, extremely difficult. The limits of the gamma phase at higher tem-

Fig. 2—Lattice Parameter of Copper-Manganese Alloys (Persson).

peratures (where it is in equilibrium with beta manganese or liquid) were easily determined by quenching experiments.

This diagram is by no means certainly established; not only is there some older microscopic evidence to show that all the alloys can be homogeneous under certain conditions, but also there is X-ray evidence to indicate that copper and gamma manganese may be isomorphous, since the face-centered tetragonal lattice of manganese may gradually change to that of copper, which can be regarded as face-centered tetragonal with an axial ratio of one. Persson¹⁹ from an X-ray study of alloys of extreme purity made from distilled manganese came to the conclusion that this was actually the case and suggested the diagram shown by dotted lines in Fig. 1.

Gayler¹⁸ found distilled manganese to melt at 1244°C. and to have transformations at 1191, 1024, 742, and 682°, but the work of Sekito²⁰ and Persson and Ohman²¹ makes it apparent that there are changes in crystal structure only at 742 and 1191°C. (Sekito gives 800 and 1100°) which corresponds to the change from alpha manganese to beta and from beta to gamma manganese. Alpha manganese has a complex body-centered cubic lattice, with 58 atoms in the unit cube, which measures 8.894 A.U.; beta is a modified simple cubic arrangement with 20 atoms in a unit cube measuring 6.300 A.U.; while gamma has the simplest structure of all, a face-centered tetragonal lattice: $a = 3.744$ A.U., $c = 3.526$ A.U., $c/a = 0.934$. A modification of manganese identical with gamma was obtained by electrolysis, although it was impossible to retain gamma by quenching from high temperatures and its structure was determined by quenching a series of copper-manganese alloys (which are stable on quenching) and extrapolating to 0% copper. The effect of dissolved copper on the structure of gamma manganese is to increase the axial ratio, and at 19% copper this becomes 1.0, the lattice then being identical with a face-centered cubic lattice. Sekito and Persson are in perfect agreement on this point. Further additions of copper to the alloy may go into solution, and since copper is itself face-centered cubic, the possibility of complete isomorphism is evident.

The lattice parameter of the entire series of alloys quenched from suitable temperatures is shown in Fig. 2, taken from the work of Persson.¹⁴ By comparing the parameter of alloys quenched from 400, 500, and 600°C. with this curve, Persson obtained the alpha boundary shown by the dotted line in Fig. 1. The curve in the most interesting portion of the diagram is, however, so extremely flat that high accuracy could not be attained. Indeed, Persson's values for the parameter beyond 40% copper are constant within ± 0.003 Å and the experimental results could be equally well satisfied by a sloping curve up to 40% manganese intersecting a horizontal straight line at this point. If this were really so, the solubility of manganese in copper would be about 40% and between 40 and 80% manganese there would coexist two phases of almost identical structure, possibly with a difference in the preferential location of the copper and manganese atoms in the gamma lattice. If copper and gamma manganese were truly isomorphous, it would seem that the axial ratio should vary continuously across the diagram rather than to change suddenly to 80%.

The results of Valentiner and Becker⁹ for the lattice parameter (which are in essential agreement with Persson except that they flatten at 3.75 instead at 3.73 Å), susceptibility and electrical resistivity are all open to the same interpretation. The data fall on fairly straight lines from about 50-80% manganese and could result from a two-phase zone just as well as from a solid solution series. The susceptibility reaches a marked maximum at about 25 atomic per cent manganese, probably due to an ordered structural arrangement. The value of the susceptibility is much higher at -188°C. than at room temperatures. The electrical resistivity at 20°C. according to Valentiner and Becker increases steadily from copper to gamma-manganese with a flattening in the curve in the range from 50-90% manganese. Schemtschushny and Petraschewitsch¹⁰ and others found a flat maximum in the curve of electrical resistance in the range 50-60% manganese and the hardness shows a similar maximum at 60-70% manganese. The thermoelectric force¹¹ and the crystal structure up to 20% manganese¹² agree with the proposed diagrams, indicating that the alloys in this range are homogeneous solid solutions.

Constitution of Copper-Nickel Alloys

N. B. Pilling* and T. E. Kihlgren*

Copper and nickel crystallize with a face-centered cubic lattice, and their alloys form a very simple series with complete miscibility of copper and nickel both in the liquid and solid states. The diagram determined by Guertler and Tammann¹ has been closely confirmed by Tafel² and stands unquestioned.

Fig. 1—Copper-nickel constitution diagram (Guertler and Tammann).

Further confirmation has been afforded by X-ray studies of the solid alloys^{3, 4, 5} from which it appears that nickel contracts the lattice parameter of copper linearly (per atom) from 3.60 Å for copper to 3.54 Å for nickel. Mention may be made of the conclusion of Gans and Fonseca,⁶ based upon the constancy of the Curie temperature and the magnetic susceptibility, that the range 45-50% nickel is heterogeneous. It has since been found⁷ that the lattice parameter changes uniformly across this range, and the assumption of heterogeneity is not substantiated.

The magnetic transformation of nickel, which is accompanied by no structural change, is depressed by copper to about room temperature at 68.5% nickel.^{1, 2} This transformation persists at sub-atmospheric temperatures and is reported to be about -170°C. at 50% nickel.^{1, 2}

Constitution of Copper-Phosphorus Alloys

By H. L. Burghoff*

Except for the determination by Guillet in 1905 of the liquidus of alloys containing up to 15% phosphorus and the freezing point curve reported in 1906 by Hlorns and Tucker, the literature, prior to the work by Heyn and Bauer in 1907, contains only results of simple chemical studies of the phosphides of copper. The earlier investigators found several phosphides of which only the one with the formula Cu_3P is of commercial importance.

Several important experimental observations were made by Heyn and Bauer. Alloys higher than 15% by weight of phosphorus cannot be prepared by fusion, but

Fig. 1—Copper-phosphorus constitution diagram.

Fig. 2—Alpha phase boundary of the copper-phosphorus constitution diagram.

must be prepared by heating copper turnings with phosphorus at a lower temperature. Alloys richer in phosphorus are unstable at high temperatures and lose phosphorus, there tending to be a definite limiting value for each temperature. Thus at 1100°C. the saturation content is 14.1% phosphorus, which corresponds to the formula Cu_3P . In rapid heating and melting of phosphorus-rich alloys, as in casting into ingots, there is not sufficient time to reach the saturation limit of 14.1%, and thus the commercial ingot of 15% phosphorus is obtained.

The constitutional diagram for alloys of copper with phosphorus up to 15% is shown in Fig. 1. Heyn and Bauer found the eutectic at 8.27% phosphorus with a melting point of 707°C., this being confirmed in 1908 by Huntington and Desch. More recent work by Lindlie places the eutectic composition at 8.38% phosphorus and the eutectic temperature at 714°C. as shown in Fig. 1.

Fig. 3—Lattice parameters for copper-phosphorus alloys.

The compound Cu_3P , containing 14.1% phosphorus, melts at 1022°C. The alloys shown above 14.1% phosphorus are composed of crystals of Cu_3P and of a second phosphide, probably Cu_2P . No solubility of copper in Cu_3P has been observed.

Heyn and Bauer placed the solid solubility of phosphorus in copper at 0.175% on the basis of their microscopic observations of slowly cooled specimens. Hudson and Law, however, placed the limit at about 1% phosphorus upon finding that a phosphor copper containing 0.9% of phosphorus by weight had an almost homogeneous structure after annealing for 2 hr. at 690°C., or 4 hr. at 640°C. In 1930 Hanson, Archbutt, and Ford investigated the solid solubility of phosphorus in copper, and reported

*Research Metallurgist, Chase Brass & Copper Co., Inc., Waterbury, Conn.

that the solubility decreased from approximately 1.2% phosphorus at 707°C. to approximately 0.5% at 300°C. Mertz and Mathewson have since established the alpha phase boundary in Fig. 1, and, on a more open scale, in Fig. 2, using X-ray methods and prolonged heat treatments of carefully homogenized material which assured equilibrium conditions. The lattice parameters determined by them are shown in Fig. 3.

In spite of the variable solubility of phosphorus in copper, capacity for precipitation hardening of copper-phosphorus alloys appears to be negligible. Hanson, Archbutt & Ford found that the Brinell hardness of quenched strip of an alloy containing 0.95% phosphorus was increased from 43 to 52 by heat treatment, but no increase in tensile strength was obtained.

Constitution of Copper-Silicon Alloys

By Cyril Stanley Smith*

The early history of the alloys of copper and silicon, some of which were made and examined by chemists over a century ago, was given by Baraduc-Muller¹ and need not be further discussed here. Hansen² reproduces and discusses all diagrams published prior to 1936.

The earliest diagram was that of Rudolfi,³ which indicated the presence of a compound Cu_3Si forming a eutectic both with silicon and with a beta solid solution, the latter decomposing to a complex compound, Cu_5Si_4 , at 710°C .

The diagram of Sanfourche⁴ was more complex and showed the existence of five distinct solid solutions, two of which underwent polymorphic changes. The alpha limit was placed at 5% between room temperature and 731°C . and about 4.3% at 845°C .

Corson⁵ discarded all previous work as incorrect and suggested a diagram which is very simple, but which does not in any way explain the thermal observations of the earlier workers. His diagram was the first to show a sloping alpha boundary.

Matuyama⁶, by electrical resistivity measurements and thermal analysis, deduced a diagram which was not greatly different from that of Rudolfi. He showed the solubility of silicon in copper to be 5.9% at 800°C . and 4.9% at room temperatures. The beta solid solution was supposed to decompose at 795°C ., while the gamma phase was formed by a peritectoid reaction at 800°C . and underwent a polymorphic change to gamma at 738°C . His delta solid solution corresponded approximately to Cu_3Si , but had a variable composition.

Fig. 1—Copper-silicon constitution diagram. See text for discussion of an additional phase not shown in this diagram existing at about 6% silicon and between 552 and 842°C .

change between 620 – 558°C . It forms a eutectic with silicon at 16.0% silicon and 802°C ., and with the delta solid solution at 9.9% silicon and 820°C .

Smith's diagram showed no horizontal at 800°C . and no phase between 9–12% silicon. Iokibe⁷ confirmed Matuyama's discovery of the horizontal at 800°C . and ascribed it to the formation by a peritectoid reaction of a phase containing 10.6–10.7% silicon, which is stable between room temperatures and 800° , but which does not form sufficiently rapidly to produce an arrest on cooling curves. By a study of the crystal structure of the alloys quenched from 550°C ., Arrhenius and Westgren⁸ independently discovered the same phase, but finding alloys quenched from 800° to be free from it, supposed it to decompose at 620°C ., corresponding to the heat evolution which had been attributed by Smith to a polymorphic transformation in the phase at 12% silicon. The break in the conductivity curves of Matuyama is so very definite that it seems probable that the higher temperature is

According to the diagram of Smith¹, the solubility of silicon in copper reaches its maximum value, $6.7 \pm 0.1\%$ silicon between 726 – 782°C . At 852°C ., the temperature of the peritectic formation of beta from liquid and alpha, the solubility is 5.25%, while below 726°C . the solubility decreases gradually to 4.0% silicon at 350°C . Beta decomposes at 782°C . to alpha and delta, while delta itself decomposes at 710°C . Gamma, which corresponds closely to the compound Cu_3Si , is formed by a peritectoid reaction at 726°C . The solid solution at about 12% silicon melts at 859°C . and suffers a polymorphic

*Research Metallurgist, American Brass Co., Waterbury, Conn.

the correct one. This phase has been shown as forming at 800°C. in Fig. 1, which is believed to represent the most probable form of diagram. In accordance with the nomenclature of Arrhenius and Westgren, the new phase is called epsilon and the phase at 12% silicon (called epsilon by Smith) becomes eta. Except for this addition the diagram is essentially that of Smith but certain other points criticized by other workers should be noted.

Arrhenius and Westgren further modified Smith's diagram by moving the beta field to a lower silicon range and changing slightly the limits of the gamma and eta phases, but their experiments, made with a limited number of alloys and at only two temperatures, do not permit the phases to be outlined very accurately. Sautner¹⁸ was unable to find the epsilon phase and proposed a number of other changes in the diagram. Part of his diagram is reproduced in Fig. 3. He considered the gamma phase to extend up to the solidus at 815°C. but there is no evidence in the other papers on the system to support this, indeed, Arrhenius and Westgren reproduce X-ray powder photographs showing clearly the co-existence of beta and delta in samples quenched from 800°C.

Sanfourche and Smith supposed eta to undergo one polymorphic transformation. Iokibe found two transformations while Arrhenius and Westgren found no change in crystal structure from room temperature to the melting point.

On account of the importance of the alpha phase, the only one which possesses considerable ductility at room temperature, the part of the diagram up to 8% silicon is redrawn on a larger scale in Fig. 2. The alpha phase boundary shown in this as well as in Fig. 1 is that of Smith which was generally accepted until Von Schwartz²² stated that there was a new phase at the limit of the alpha. Sautner¹⁸ in a more detailed study introduced this phase in the diagram at about 6% silicon extending from 700-830°C., where it was supposed to melt peritectically at the same temperature as the beta phase—a thermodynamic impossibility. In the part of Sautner's diagram reproduced in Fig. 3 his phases have been renamed in accordance with Fig. 1 and 2 to avoid confusion and the new phase which he calls beta is here labeled "X." According to Sautner the alpha boundary runs between 5.1% at 700°C. and 4.9% silicon at 830°C. and decreases to 4.2% at 400°C. The new phase seems to be the same as that first noticed by Voce²³ in the ternary copper-silicon-manganese system. Isawa²⁴ has confirmed its existence röntgenographically but believes it to be stable at room temperatures.

The system is now (Nov. 1938) being reinvestigated in the writer's laboratory by microscopic and thermal methods. The beta peritectic remains at 852°C. The new phase has a wider range of existence than Sautner suspected. It forms from alpha and beta by a peritectoid reaction at 842°C. and contains 5.9% silicon at this temperature. The silicon-rich boundary of the phase is essentially the same as that shown for the limit of the alpha phase in Fig. 2 until at 552°C. and 5.2% silicon the phase decomposes to an alpha + gamma eutectoid. The alpha phase boundary slopes lineally from 5.30% at 842°C. to about 4.6% at 552°C. and about 3.8% at 400°C.

Fig. 2.—Copper-silicon constitution diagram up to 8% silicon. See text for discussion of additional phase containing about 6% silicon not shown in this diagram, and a new location of the alpha boundary.

Very unusual structures are observed in the two-phase region, for the alpha and "X" phases co-exist as fine twin-like lamellae and show no tendency to spheroidize on annealing.

Fig. 3—Copper-silicon constitution diagram after Sautner.

Crystal Structure—The crystal structure of all the phases has been studied by Arrhenius and Westgren¹¹ and the alpha phase by Davey,⁸ Bain,⁹ and Kaiser and Barrett.¹² The last named investigators give the values in the table below for the parameter of the face-centered cubic lattice of the alpha solid solution quenched from 725°C. Sautner believes the structure of the new "X" phase at about 6% silicon to be hexagonal close packed, with $a_0 = 2.40$ Å and the unit cell containing 16 atoms of copper and silicon. This is manifestly impossible since such a cell is not large enough to contain even six copper atoms. Isawa²⁰ considers it to be hexagonal with $a = 2.552$ Å, $c/a = 1.628$. According to both Arrhenius and Westgren, and Sautner, the beta phase is hexagonal close packed in structure, $a_0 = 2.59$ Å $c/a = 1.633$.

The gamma phase is supposed by Arrhenius and Westgren to have the cubic structure typified by beta manganese, and contains 20 atoms in a unit cube of 6.21 Å edge. Silicon and copper must be interchangeable in the structure if this is so,

% Silicon	Lattice Parameter A. U.	% Silicon	Lattice Parameter A. U.
0	3.6078	5.02	3.6150
1.09	3.6103	5.91	(3.6151)
3.01	3.6128	6.36	(3.6157)

for no integral number of Cu₂Si groups can be fitted in the cell. The delta structure could not be determined but is apparently of a distorted gamma brass type.

The structure of the epsilon phase, first described by Arrhenius and Westgren as being cubic with 76 atoms (4 groups of Cu₂Si) in a cube measuring 9.694 Å edge, was later completely solved by Morral and Westgren²¹ who assigned the space group T_h² (I $\bar{4}$ 3d). Sautner did not find a homogeneous phase in this region but ascribed a similar structure to the eta phase at high temperatures.

Arrhenius and Westgren found that the eta phase had a diffraction pattern partly accounted for by a hexagonal structure derived from a body-centered cubic lattice of gamma brass type but this did not account for all lines. Sautner considers this to be a tetragonal body centered lattice, $a = 9.21$ Å, $c/a = 1.14$.

Silicon²² has a diamond cubic structure, 5.418 Å, parameter. Its melting point has recently been redetermined as 1410°C. for metal of from 99.89% purity,²³ and Gayler²⁴ has given the temperature of 1415°C. as the melting point of a sample containing 99.93% silicon.

Mehl and Barrett²⁵ have studied the mechanism of precipitation of the gamma phase from alpha. They find it forms in thin plates on an indeterminate family of planes of high indices, showing as many as twelve directions on a section.

Constitution of Copper-Silver Alloys

By Cyril Stanley Smith*

The copper-silver system was one of the earliest to be examined by scientific methods. Roberts-Austen¹ determined the liquidus curve in 1875, while in 1897 Heycock and Neville² determined a diagram which has been changed but little by more recent researches. Levil,³ on account of the fact that an alloy of 72% silver solidified without segregation, supposed this alloy to be the compound Ag_2Cu , but later work has shown this to be a eutectic.

The liquidus curve has been determined by Heycock and Neville,² Friedrich and Leroux,⁴ Hirose,⁵ and Broniewski and Koslacz,⁶ all of whose results are in substantial agreement. Hirose's results on the silver-rich section of the liquidus are somewhat below those of Friedrich and Leroux, whose curves, agreeing closely with that of Heycock and Neville, are used in the composite diagram, Fig. 1. Friedrich and Leroux gave the eutectic temperature as 778°C. at 72% silver; Heycock and Neville, 779° at 71.9%; Hirose, 778° at 71.5%, and Broniewski and Koslacz, 779° at 71% silver. Roeser,⁷ with a view of establishing the eutectic temperature definitely so that it might be used as a secondary standard for the calibration of pyrometers (for which it is admirably suited) determined the temperature with great accuracy and stated it to be $779.4 \pm 0.1^\circ\text{C}$. Stockdale⁸ in a careful study of a number of eutectics gave the composition of that in the copper-silver system as 71.94% silver, which value is probably the most accurate that has been published.

The solid solubility limits have been determined by a number of observers, although with conflicting results. Friedrich and Leroux gave the composition of the saturated solutions as 1 and 94% silver respectively, while the results of the annealing experiments of Lepkowski⁹ were 6 and 95% silver at 750°C. The electrical resistance of the alloys has been determined, amongst others, by Kurnakow, Puschin and Senkowsky,¹⁰ whose curves indicate the solubility limits to be at 6.5 and 94.8% silver respectively, in alloys which were annealed and slowly cooled.

Silver-Rich Alloys—The observation of Fraenkel,¹¹ independently confirmed by both Norbury¹² and Leach and Chatfield,¹³ that sterling silver can be hardened by heat treatment proved that the solubility must change with temperature, and the investigations of Fraenkel and Schaller,¹⁴ Haas and Uno,¹⁵ Johanssen and Linde,¹⁶ Wienbaum,¹⁷ and Hansen¹⁸ confirm this. Fraenkel and Schaller worked principally with the 8% silver alloy, but they found that an alloy with only 2.84% copper could be age-hardened after long annealing at 280°C., and therefore the solubility is less than this amount. Johanssen and Linde determined the electrical conductivity of a number of alloys after annealing both for 90 hr., at 750°C. and 100 hr. at 350°C., followed by quenching. The breaks in their curves correspond to solubility limits at 8.2 and 93.8% silver respectively at 750°C., and 1.7 and 97.6% silver at 350°C. Hirose¹⁹ gives a complete diagram in which the solubility of silver in copper at the eutectic temperature is shown at about 5%, and of copper in silver at 6%, both solubilities decreasing rapidly to a negligible amount at 600°C. Broniewski found the solubility limits at 779° to be 6% and 93% silver. Moller by electrical conductivity determinations found the solubility of silver in copper to be 6% at 728°, decreasing to 3.9% at 529°C.

The work of Hansen¹⁸ was the first in which the solubility of copper in silver was determined with a high degree of accuracy. By microscopic examination of quenched and reannealed samples he found that the solubility of copper in silver was 9.0% at the eutectic temperature, decreasing to 1.7% at 300°C. By determining the

parameter of selected alloys quenched from a high temperature and reheated at a series of lower temperatures, and comparing the observed values with the curve of

Fig. 2—The silver-rich portion of the Copper-Silver Equilibrium Diagram.

formation in an alloy containing 0.79% copper. In the complete diagram, Fig. 1, and the larger scale reproduction of the silver corner, Fig. 2, the results of Ageew and Sachs have been preferred in the low temperature ranges on account of the greater sensitivity of their method, while the curve above 500° is drawn as an average curve through both their experimental points and those of Stockdale. The solubility will be seen to be 8.8% copper at the eutectic temperature, decreasing in a smooth curve to 0.3% at 200°C. The solidus shown is that of Stockdale.

Copper-Rich Alloys—The investigations on the solid solubility at the copper end of the diagram by Stockdale²⁸ (microscopic and electrical resistance methods), Ageew, Hansen and Sachs²¹ (X-rays), Smith and Lindlie²⁹ (microscopic) and Wiest³⁰ (X-rays) gave results which differed by not more than 0.5% at any temperature. Owen and Rogers³⁰ give a solubility curve, based on lattice parameter higher solubility at 700°C. at both ends

Fig. 4—The lattice parameter of the silver-rich silver-copper alloys.

that of Ageew and Sachs, outlined above, but using single-crystal wires of the alloys, found a solubility from 1.5-2% greater than in polycrystalline material, for which his results are in agreement with those of the other investigators. Doubt was thrown upon this conclusion by Schmid and Siebel,³¹ and after some controversy,³² Wiest³⁰

parameter vs. composition for a series of alloys with different copper contents quenched from 780°C., Ageew and Sachs²¹ were able to determine precisely the amount of copper in solution at each of the reannealing temperatures employed. They found the solubility to be somewhat less than Hansen showed, but their figures were practically confirmed by the work of Stockdale²⁸ who used microscopic methods at high temperatures and electrical conductivity studies below 550°C. The agreement above 500° between the investigations of Stockdale and Ageew and Sachs, which were carried out independently and by different methods, is so good that there is little doubt of the solubility at the higher temperatures, but below 500° Stockdale's figures for the solubility are somewhat higher, and he was unable to find a trans-

Fig. 3—The copper-rich portion of the Copper-Silver Constitution Diagram.

measurements, which shows somewhat of the diagram than other investigators show. Surprisingly, the microscopic study of Smith and Lindlie²⁹ gave the lowest solubility, although this method usually indicates a solubility rather higher than the true one. The solid-solubility curve shown in Fig. 1 and on a larger scale in Fig. 3 is drawn as an average through the experimental points of all four investigations and cannot be far from the true value. The solidus curve drawn is that of Smith and Lindlie. Stockdale's solidus curve is 50° higher at 7.5% silver and drops very rapidly to meet the eutectic line at 8.3% silver.

Wiest, using a method similar to

attributed the result to segregation, and gave new values for the parameter of single and multicrystalline material which were identical. At the same time, however, he found differences in parameter in the two-phase zone which indicated that the solubility was appreciably greater in single crystals.

Crystal structure determinations by X-ray means have been carried out by Sacklowsky,¹³ Erdal,¹⁴ Wienbaum,¹⁵ Ageew, Hansen and Sachs,¹⁶ Ageew and Sachs,¹⁷ Megaw,¹⁸ Wiest,¹⁹ and Owen and Rogers.²⁰ The results of Ageew and Sachs for the lattice parameter of the silver-rich solid solutions are shown in Fig. 4, and Ageew, Hansen, and Sachs' figures for the copper end of the diagram in Fig. 5. The face-centered cubic lattice of silver has a parameter of about 4.078 Å, a value which changes to 4.029 with 8% copper in solution. If an alloy is annealed at a temperature where it is no longer homogeneous, the excess copper will be precipitated and the parameter of the parent silver lattice will increase to a value corresponding to

Fig. 5—The lattice parameter of the copper-rich silver-copper alloys (Ageew, Hansen, and Sachs).

that of an alloy of composition equal to the solubility limit at that temperature, regardless of the amount of copper in excess. The curve for parameter vs. copper content, therefore, consists of a horizontal straight line intersecting the sloped parameter curve at a point corresponding to the solubility at the temperature of annealing. In Fig. 4 are shown several such lines, corresponding to various temperatures.

Copper is also face-centered cubic, and has a parameter of about 3.608 ± 0.001 Å at 20°C. Additions of silver in solution up to

the solubility limit at 770°C. increase this to 3.632 Å. The X-ray diffraction pattern of alloys in the duplex range of the diagram shows lines due to both of the phases present, the parameters depending on the temperature at which the sample has been annealed and quenched, while the intensity of each set of lines will depend on the relative amount of copper and silver-rich phases present.

Constitution of Copper-Tin Alloys

By Dr. Samuel L. Hoyt*

The copper-tin alloys were among the earliest to be studied experimentally and their historical significance gives them a special place in our list of metallic alloys. The first systematic investigations were those of Roberts-Austen, Stansfield, and Campbell for the Alloys Research Committee of the Institution of Mechanical Engineers. This work was followed immediately by the publication of the diagram of Heycock and Neville, the feature of which was the use of the principles of the phase rule, to parallel a similar treatment by Roozeboom of the early iron-carbon diagram. Shepherd and Blough, in this country, and Giolitti and Tavanti in Italy soon followed with their contributions. It is interesting to note that this early work, and particularly the now classical contribution of Heycock and Neville, gives a satisfactory understanding of this system, though certain features were left unsettled which still remain controversial today.

In 1913 the writer showed that a heat effect occurred in the alloys over the alpha plus gamma range (Fig. 1) at 590°C. which had previously been missed. Subsequent work by British, German, Japanese, and American investigators has added to our knowledge of this system, while the methods of X-ray crystal analysis have been applied to a study of the phases. The most recent findings are that on long time annealing, (a) the solubility of tin in copper decreases at lower temperatures and (b) the delta phase, of Cu_3Sn , changes to alpha plus eta, or Cu_5Sn , at about 330-350°C.

The copper-rich portion of the copper-tin diagram is reproduced in Fig. 1. This is essentially the diagram of Heycock and Neville¹ and was laid down by melting point determinations and by microscopic examination of heat treated samples for the determination of the fields within the solid state. The more important features of the constitution of this system may be listed as follows:

(1) Tin lowers the melting point rather rapidly from 1083°C. for pure copper to $795 \pm 5^\circ\text{C}$. at 25% tin. Above 25% tin the effect is less pronounced.

(2) The first additions of tin enter copper in solid solution to form the alpha or common low-tin bronzes. The amount of tin which is dissolved is not over 16%, which is the saturation concentration,² but is much less than this for ordinary cooling rates. The apparent solubility is about 5% tin for chill castings and is in the neighborhood of 10% for slowly cooled alloys. It may be increased to more than this by moderate annealing operations. The pronounced dendritic character of these alloys is responsible for these variations and gives the typical microstructure. In published diagrams there is lack of agreement for the limit of the alpha field, but the location is purely arbitrary unless the saturation value of 16% is used. In reading the diagram given here, it is to be borne in mind that the common structure of low-tin bronze is definitely dendritic and that the apparent limit of solubility is well below that given by the vertical, dotted line at 16% tin (for a discussion of this line, see below).

(3) Two peritectic reactions or equilibria occur over this range of tin at which new solid phases become stable with the melt. The solid phases are known as alpha, beta, and gamma. The alpha phase has been discussed. The beta and gamma phases are responsible for transformations in the solid state. Heycock and Neville were not able to distinguish microscopically between these two phases and this has been confirmed by Matsuda.

(4) When the tin content exceeds that which is present in the alpha solid solution, the excess forms a typical eutectoid structure of alpha and delta by the eutectoid transformation, $\text{gamma} = \text{alpha} + \text{delta}$. When the tin content is in the neighborhood of 10% or less, the delta phase can be eliminated by ordinary annealing.

(5) Over the range of composition which is covered here there is one more room temperature phase, the intermetallic compound Cu_5Sn . With additional tin in solid solution it is the phase, eta, of the diagram. This phase is polymorphic and transforms into gamma at 670°C. The delta phase has been considered to be an intermediate solid solution, rather than an intermetallic compound, mainly because its physical properties did not fit the current conceptions of compounds. More recently X-ray crystal analysis shows that this phase must be the compound,

*Director of Metallurgical Research, A. O. Smith Corp., Milwaukee.

Cu_3Sn . The ranges of composition of the phases delta and eta are not known definitely.

(6) An interesting feature of the copper-tin alloys is the partial fusing of those containing just above 40% tin, after having once solidified completely.

The first 6 features have been well established and they are generally accepted. There are some additional features which have not been definitely settled by the work which has been done to date. Fortunately, for the practical handling of these alloys they give no difficulty from that score.

(7) A thermal critical point was discovered by the writer, in the alloys from 12-26% tin at 580°C . This point has been verified by the Bureau of Standards and by various others since then. The transformation which is responsible for this heat effect has been the subject of considerable experimentation and discussion. The writer found that the maximum heat effect was well towards the right of the alpha plus gamma field of Fig. 1. It was held that the effect was associated with the beta phase and he suggested the eutectoid change of beta as a possible explanation. However, it was not until Bauer and Vollenbrück conducted their careful

Fig. 1—Copper-rich portion of the copper-tin constitution diagram.

study of this system that the construction of Fig. 1 could be held to be adequately supported.⁴ The major objection to this construction has been the failure to observe a typical eutectoid structure but this objection is no more serious here than it is in the case of the corresponding situation with the eutectic which lies close to one of the components. Other investigators have published results which do not agree with the construction of Fig. 1 and have suggested different explanations for the heat effect at 580°C . Noteworthy among these is that of Isawa⁵ who concluded from X-ray evidence that beta undergoes a change in superstructure at this temperature. This idea appears to be supported by the microstructure of these alloys but does not agree with what one would expect from a study of the ternary alloys with zinc which show a large heat effect at this temperature and a phase change.⁶

(8) The gamma phase of composition Cu_3Sn has been assumed to solidify over a range of temperature (Heycock and Neville, Shepherd and Blough) while Giolotti and Tavanti, and Bauer and Vollenbrück⁴ record a constant freezing point for this composition. Matsuda⁷ likewise checked this point, as did the writer, and came to the same conclusion. This latter construction has been incorporated in the diagram, and is consistent with physical tests made on the molten copper-tin alloys which indicate the presence of this compound in the liquid state. Hamasumi and Nishigori also checked this point, but concluded that it was an alloy with lower tin content that had the constant freezing point.⁸

(9) The transformation at 580°C , involving delta has been variously explained, and is usually associated with a eutectoid or peritectoid change, or with both.

In the last case, a second horizontal is shown. It is not possible to represent the phase relationships in this region in a way which reconciles the conflicting opinions. The construction shown is that used in a number of recent diagrams.

The most drastic change in the equilibrium relations of the copper-tin alloys is introduced in the diagram of Fig. 1. Owen and Iball,⁹ Owen and Williams,¹⁰ and Haase and Pawlek¹¹ have shown that the alpha solid solution precipitates delta at temperatures above 330-350°C. and eta below that temperature. The alpha phase shifts its saturation concentration about as is shown by the solid line. This occurs only with prolonged annealing and the usual microstructure occurs in accordance with the statements in point (2). For this reason the dotted vertical at 16% Sn is used while the metastable structures are indicated in [].

The difficulties involved in the experimental and theoretical elucidation of the controversial features of this system are rather great, and this accounts for the lack of agreement among the published diagrams. More recent work suggests that the diagram is much more complicated than that of Fig. 1. Referring to paragraph 9 above, for example, Hamasumi and Nishigori¹² report two eutectoids and two peritectoids for that region alone and their construction was based on a careful and detailed study of the constitution of this system.

The methods of X-ray crystal analysis have been used to show the atomic arrangement of the phases of this system. The alpha solid solution is face-centered cubic while the lattice parameter increases from 3.608 Å for pure copper to 3.695 Å for 15% tin alloy.⁹ Mehl and Barrett¹³ have shown that the tin atoms occupy positions on the copper lattice, by substitution. The next phase is delta, and it has a face-centered cubic atomic arrangement with 416 atoms per unit cell and a lattice parameter of 17.92 Å. This is the same structure as that of gamma brass in which it was first discovered and X-ray metallographers use the name gamma for this phase of the copper-tin system, and for all others of the same structure. This work showed that this phase is not Cu₃Sn, but Cu₁₁Sn₃. The phase Cu₃Sn, or eta, has a hexagonal close packed arrangement with 62 atoms per unit cell, $a = 2.75$ Å, and $c/a = 1.57$. (See also reference 10.) This arrangement was first found in the epsilon phase of brass and hence this copper-tin phase, and all others of the same structure, have been given the common name of epsilon. The high temperature phase gamma has the same body-centered cubic arrangement as beta brass with a parameter of 2.972 Å so that this, and other similar phases, are called beta.¹⁴

The Constitution of the Copper-Zinc Alloys

By Arthur Phillips* and R. M. Brick**

With the exception of a few isolated references to the solubility of zinc in copper, the literature on the copper-zinc constitution diagram offers little of significance prior to 1896 when Charpy¹ reported the results of a study of the microstructure and mechanical properties of brasses containing up to approximately 50% zinc. In 1897, Roberts-Austen² published the first complete liquidus curve together with the several peritectic horizontals. He also indicated a "eutectic" at 450°C. in alloys containing 25-45% zinc. In a second paper, Charpy³ questioned the presence of the eutectic. This subject was the basis of a controversy which has persisted to the present day.

Shepherd⁴ offered the first complete constitutional diagram which was assembled from data obtained by thermal and microscopic analysis. Subsequent investigators have made free use of this diagram. Shepherd, however, failed to find the 450°C. horizontal reported by Roberts-Austen. Guillet's⁵ results were essentially a verification of Shepherd's work. Tafel⁶ and Parravano modified Shepherd's liquidus and solidus curves. Tafel also believed Roberts-Austen to have been in error with regard to the 450°C. horizontal.

Carpenter and Edwards⁷ proved without question the presence of the transforma-

Fig. 1.—Constitution of copper-zinc alloys.

tion point found by Roberts-Austen and attributed it to a eutectoid inversion of beta into alpha plus gamma. In two later papers Carpenter,^{8,9} offered photographic evidence which seemed to prove his contention that beta brass below 470°C. consists of alpha and gamma associated in a state of division just within the resolving power of the microscope. Hudson¹⁰ rejected Carpenter's interpretation in favor of an explanation based on a polymorphic transformation of beta into a beta modification which could not be distinguished from beta by microscopic examination.

Mathewson and Davidson¹¹ determined the boundary curve between the alpha and the alpha plus beta fields; they also indicated the curve separating the beta and the alpha plus beta fields on the basis of experimental results obtained in the Hammond Metallurgical Laboratory, but not reported in their paper. Matsuda¹² published an incomplete diagram extending from 70-30% copper, assembled from microscopic and physical data. A month later, Imai¹³ presented a diagram based entirely on electrical resistance measurements. Both Matsuda and Imai suggested that the beta transformation is associated with no change of phase but consists of a change in atomic energy, analogous to Honda's interpretation of the A_2 transformation in iron. Masing,¹⁴ Helke and Ledebur,¹⁵ and Andrew and Hay¹⁶ published none too convincing evidence in favor of the eutectoid inversion of beta.

Genders and Bailey¹⁷ by microscopic examination of brasses annealed after chill casting extended the limit of the alpha phase to a lower copper content than that

*Prof. of Metallurgy and **Instructor of Metallurgy, Yale University, New Haven.

determined by Mathewson and Davidson; they placed the solubility of zinc in copper at 39% at 400°C. Their alpha limits were later confirmed by Gayler.³⁰ Haughton and Griffiths³¹ by electrical resistivity measurements determined the beta transformation temperature in brasses containing 46-62.6% copper. Their work showed conclusively that the temperature became higher as the zinc concentration of brasses containing beta increased, as had been previously suggested by Mathewson and Davidson and others.

Jitsuka³² and Bauer and Hansen³³ offered complete revisions of the copper-zinc diagram. The latter authors made a critical review of the literature and their diagram composed of accepted data, supplemented by a large amount of original work, undoubtedly represents the most authoritative work on the subject. Jitsuka suggested a double transformation of the beta constituent $B \rightleftharpoons B_1 \rightleftharpoons B_{11}$. Schramm has investigated the peritectic temperatures and concentrations. In general, his results are in agreement with the results of Bauer and Hansen.

X-ray investigation by means of lattice parameter measurements have been carried out by a number of workers^{34, 35, 36, 37} and are in fair agreement with the findings by other methods. Studies of the structure of the alpha phase have been made by Bain;³⁴ of the beta by Westgren and Phragmén,³⁵ Owen and Preston,³⁶ and Phillips and Thelin;³⁷ of the gamma by Bradley and Thewlis³⁴ from Westgren and Phragmén's data and more recently by Bradley and Gregory;³⁸ the epsilon and eta by Westgren and Phragmén³⁵ and Owen and Preston.³⁶

Table I
X-Ray Data

Phase	Structure	Lattice Constants Å
Alpha	Face-centered cubic.....	100% Cu = 3.608
Beta	Body-centered cubic, CuZn.....	62.5 Cu = 3.693
Gamma	Cubic-low symmetry, 52 atoms/cell, Cu ₅ Zn ₈	2.942
		2.949
		8.837
		8.874
Epsilon	Hexagonal close packed.....	Saturated with Zn at 200°C.
		a ₀ = 2.762
		c ₀ = 4.308
		c/a = 1.560
Eta	Hexagonal close packed.....	2.6% Cu
		Zn
		2.6732 2.6590
		4.8125 4.9351
		1.8012 1.8560

It was believed by Straumanis and Weerts³⁹ and von Steinwehr and Schulze⁴⁰ that the beta-beta prime transformation is a change in atomic distribution, probably from a random to an orderly arrangement. Moser,⁴¹ Mott⁴² and Sykes and Wilkinson⁴³ assumed the ordering to be analogous to that found in Cu₃Au, with copper atoms situated at the cube corners and zinc atoms at the cube centers. On this basis, the experimentally determined specific heat change during the beta-beta prime transformation was found to be in good agreement with the energy changes predicted by order-disorder theories, particularly the local ordering of Bethe. Recently Jones and Sykes⁴⁴ using X-rays of zinc K radiation have obtained photographs which show superlattice lines, thus producing the first direct evidence of an ordered structure in beta prime at room temperature. According to Kaminski and Kurdjumow another transformation to a face-centered tetragonal ordered structure occurs in beta brass at -14°C. The new structure, designated alpha prime, has the dimensions, a = 3.755, c = 3.586, c/a = 0.955.

In Table I are compiled the most recent and probably the best data on structure and the lattice constants at room temperature at the concentration limits of each phase. Compound forms on which the phases are based are also listed where known.

The diagram of Fig. 1 has been assembled from data carefully selected from many of the sources previously mentioned. It is difficult to make adequate and detailed acknowledgments of the many investigators contributing to this diagram. Certain specific statements may be made, however, relative to the selection of boundary lines in the parts of the diagram containing alloys of industrial importance.

The alpha and beta liquidus and solidus lines have been drawn from the

combined data of several works, particularly Parravano and Tafel. Bailey and Gender's work, confirmed as it has been by others, has been accepted in placing the alpha solubility curve. The course of the beta transformation, extending from 453-470°C. from the alpha to the gamma solubility curves has been taken from the data of Haughton and Griffiths. A double line extending through the beta field, represents a narrow B + B₁ field, as originally shown by Mathewson and Davidson and more recently by Bauer and Hansen. The zinc-rich end of the diagram has been accepted as offered by Anderson, Fuller, Wilcox, and Rodda.¹² The remainder of the work has been largely derived from the results of Jitsuka, and Bauer and Hansen. The diagram, Fig. 1, is in good agreement with that published by Hansen,¹⁴ whose recent book should be consulted for complete references to all work on Cu-Zn alloys up to 1936.

Certain important concentration and temperature limits have been assembled in Table II:

Table II
Concentration Limits and Temperatures of Peritectic Horizontals

	Copper, %	Temp., °C.
Alpha + Liquid.....	67.5-63	-61.5
Beta + Liquid.....	43.5-	-39.3
Gamma + Liquid.....	30.0-27.0-19.5	697
Delta + Liquid.....	23.5-21.5-11.5	594
Epsilon + Liquid.....	12.5- 2.7- 1.9	424.5
Eutectoid $\delta \rightleftharpoons \gamma + \epsilon$	29.5-26.0-21.5	555

Concentration Limits at 400°C.			
	Copper, %	Copper, %	
Alpha	100.0-61.0	Epsilon	21.5-13.5
Beta	54.5-50.0	Eta (424°C.)	2.66-0
Gamma	41.5-32.5	Eta (100°C.)	0.40-0

Constitution of Copper-Nickel-Tin Alloys

By J. T. Eash*

Investigations of the constitution of alloys of copper-nickel-tin have for the most part been limited to alloys of high copper content. While considerable controversy exists over certain features of the binary copper-tin diagram, the most important being the beta and gamma transformations and the exact domain of the alpha solid solution at low temperatures, the various investigations of the ternary copper-nickel-tin alloys are qualitatively in agreement, with the possible exception of the alpha domain only at low temperatures and the nature of the secondary phase in alloys just exceeding the alpha boundary (references 1-4).

Fig. 1—The copper-tin constitution diagram. Fig. 2—Constitution diagram for nickel-copper-tin alloy with 2% nickel. Fig. 3—Constitution diagram for nickel-copper-tin alloy with 5% nickel. Fig. 4—Constitution diagram for nickel-copper-tin alloy with 10% nickel.

Due to the complexity of the relations existing in the ternary system, the constitution of the alloys of copper-nickel-tin is most readily considered from a standpoint of quasibinary sections at constant nickel levels. The equilibrium relations existing in nickel-free copper-tin alloys is represented in Fig. 1 which is a combination of the diagrams of Stockdale⁵ and Bauer and Vollenbruck⁶ and similar to the diagram presented by Hoyt on page 1364. A diagram of the equilibrium relations existing in the ternary alloys through a section at 2% nickel, as determined

*Research Metallurgist, Research Laboratory, International Nickel Co., Bayonne, N. J.

by Eash and Uphengrove,³ is shown in Fig. 2. The addition of nickel causes a marked decrease in the solubility of tin in the alpha phase and the resultant separation of a secondary phase, theta, which has been found through the use of polarized light to differ from the delta phase of the higher tin content alloys. The transition of the beta phase to alpha + gamma, which occurs at 587°C. in binary copper-tin alloys, takes place in 2% nickel alloys over a range in temperature as shown by the alpha + beta + gamma field. The beta transformation does not yield a eutectoidal structure of alpha + gamma but is merely a change to these two phases in a step-wise transition in which beta transforms to gamma which has a lower affinity for copper and allows the separation of alpha. The area of the beta field is smaller and the beta + gamma field is wider than the corresponding areas in the binary copper-tin system. The inversion of gamma to alpha + delta prime occurs at 539°C. which is 19° higher than in nickel-free alloys. The alloys of high tin content in the alpha + delta prime field have a eutectoidal structure while alloys in this field having a lower tin content (16-20%) may or may not develop a eutectoidal structure depending on the rate of cooling. A slow rate of cooling is inductive to the formation of clear delta prime while a relatively more rapid rate produces the alpha + delta prime eutectoid. The delta prime phase is distinguished from the other constituents by the structure observed under polarized light which indicates

Fig. 5—Liquidus temperatures of copper-nickel-tin alloys (Veszelka, Eash, and Uphengrove). Fig. 6—The 300°C. isotherm and the alpha-phase boundary at 780°C. (Eash and Uphengrove).

that it is anisometric. The theta phase is isometric. While delta of the straight copper-tin alloys has the same appearance as delta prime under ordinary microscopic examination, the former differs in being face-centered cubic with 416 atoms to the unit cell⁷ and gives an isometric reaction under polarized light. A small amount of nickel is sufficient to change this cubic structure to perhaps a tetragonal or a hexagonal phase.

The addition of 5% nickel produces the changes shown in Fig. 3. The liquidus and solidus temperatures shown in this section are a combination of the work of Veszelka⁴ and Eash and Uphengrove³ while the solid transformations are from the work of the latter only. The alpha + beta + gamma domain is restricted to higher temperatures as the nickel is increased until at some 7% nickel the beta phase is no longer present and the alpha + gamma field then extends up to the solidus plane. The delta prime phase in the 25-30% tin, 5% nickel alloys is clear and not eutectoidal after slow cooling.

A section at 10% nickel showing the liquidus and solidus temperatures, as given by Veszelka, and the alpha phase boundary as determined by Eash and Uphengrove is given in Fig. 4. While the liquidus temperature is raised gradually with each addition of nickel as shown in Fig. 5, the peritectic horizontal of the alloys containing 14-25% tin is not raised appreciably until nickel additions exceed 10%. In

alloys containing up to 10% nickel the solidus horizontal remains at 800°C., but the addition of 15% nickel raises it to 865°C. The annealing of heterogeneous castings must therefore be carried out at temperatures below 800°C.

A ternary diagram showing the phases existing at 300°C. (572°F.), together with the alpha phase boundary at 780°C. (1436°F.) is given in Fig. 6. Due to the changes in solubility of tin in the alpha phase with variations in temperature, the alloys in the heterogeneous alpha + theta field may be age hardened. It has been demonstrated that a wide range of these alloys are subject to age hardening, the range extends at least up to 40% nickel and 11% tin.^{1,2,3,4} By the proper selection of composition and heat treatment very striking and useful properties may be secured, the increase in hardness and proportional limit coupled with good ductility being especially noteworthy.

Constitution of Copper-Nickel-Zinc Alloys

T. E. Kihlgren*

Until recent years our knowledge of the constitution of these alloys was limited to alloys containing up to about 20% nickel and 70% zinc, (with the exception of the work of Tafel in 1908 who reported the liquidus for the entire system) and was due to the work of several investigators^{1, 2, 3}, especially Bauer and Hansen.⁴ In 1935 J. Schramm¹⁴ published a comprehensive treatise presenting the results of thermal, microscopic and X-ray investigations of the entire system. The diagrams presented in this article are those of Schramm re-orientated so that the base line

Fig. 1—Liquidus temperatures in °C. copper-nickel-zinc system (Schramm¹⁴).

will represent the binary copper zinc alloys, since the commercially important nickel silvers are essentially brasses containing up to 25% of nickel.

The liquidus surface of the copper-nickel-zinc system is shown in Fig. 1 and the constitution of the alloys at 775°C., 650°C., 25°C. in Fig. 2, 3, 4. With the exception of the alpha phase boundary at 400°C. (and 25°C.), Schramm¹⁴ and Bauer and Hansen⁴ are in good agreement on the location of the boundaries of the alpha, alpha + beta, beta, and beta + gamma fields for temperatures up to 800°C. and alloys containing up to 20% nickel, beyond which nickel content Bauer and Hansen present no data.

From Fig. 2, 3, 4, it may be seen that the face-centered cubic alpha phases of the binary systems Cu-Zn and Ni-Zn form a continuous solid solution, the alpha domain narrowing somewhat with decreasing temperature.

The beta phase of the copper zinc system, stable below 470°C., is body-centered cubic β_1 and that of the nickel-zinc system, stable below 875-800°C., is of the Au-Cu type of tetragonal lattice and designated β_2 . Schramm therefore indicates a two phase field in the ternary system in which β_1 and β_2 are co-present. The area of the two-phase field is sharply restricted at 775°C., and broadens moderately, and shifts to higher copper contents with decreasing temperature. According to Schramm, nickel raises the temperature of the β to β_1 transformation of the Cu-Zn binary system until it coincides with the solidus and disappears. Schramm does not indicate the transformation in the sections at 650 and 775°C. (Fig. 2 and 3),

*Metallurgist, The International Nickel Co., Inc.

but simply shows the β' phase to be shifted to higher nickel concentrations as the temperature is raised.

The gamma phase is common to the entire system, the gamma phases of the binary systems forming a continuous solid solution. The structure is indicated as a cubic of low symmetry (52 atoms per cell). Bauer and Hansen,⁸ Yamaguchi,¹² and Schramm¹⁴ are all agreed on the isomorphism of the gamma phases of the Cu-Zn and Ni-Zn systems.

A three-phase region exists on either side of the $\beta' + \beta_1$ two phase field, between room temperature and some temperature slightly in excess of 650°C., the one field containing α , β' and β_1 , and the other γ , β' and β_1 , both of these fields apparently increasing in area and shifting to lower nickel contents with decreasing temperature. At 775°C., the $\gamma + \beta' + \beta_1$ field is not indicated since the β_1 field exists over a very small area and does not meet the $\beta' + \gamma$ phase field boundary. According to Schramm's interpretation, some of the 13-15% nickel extrusion alloys might be expected to contain α , β' and β_1 at room temperature under equilibrium conditions, although if such is the case no mention has been made of it in the literature. At 400°C. the $\alpha + \beta' + \beta_1$ field has been shifted to beyond the range of composition of the commercial nickel silvers.

The phase relationships in the zinc corner of the diagram at room temperature are rather complicated, as may be observed from Fig. 4. The phase of the nickel zinc system designated by Schramm as delta, and possessing an hexagonal lattice, is reported to form an unbroken solid solution with the delta phase of the copper-zinc system (stable above 555°C.). At room temperature (Fig. 4) the delta field of the ternary system is extremely narrow and extends to about 10% of copper. The close packed hexagonal epsilon phase of the copper-zinc system takes up very small amounts of

Fig. 2—Constitution of copper-nickel-zinc alloys at 775°C. (Schramm¹⁴).

Fig. 3—Constitution of copper-nickel-zinc alloys at 650°C. (Schramm¹⁴).

(stable above 555°C.). At room temperature (Fig. 4) the delta field of the ternary system is extremely narrow and extends to about 10% of copper. The close packed hexagonal epsilon phase of the copper-zinc system takes up very small amounts of

Fig. 4—Constitution of copper-nickel-zinc alloys at 25°C. (Schramm¹⁴).

nickel into solid solution. Since the solubility of nickel in zinc is of the order of 0.04%, and of copper in zinc about 0.3% (at 100°C.), the eta phase domain of the copper-nickel-zinc system is exceedingly small. The lattice of the eta phase is of the close packed hexagonal type.

The Ternary System Copper-Zinc-Tin

By H. C. Jennison* and Cyril Stanley Smith†

In spite of the fact that it is one of the most important ternary nonferrous systems, the constitution of much of the copper-zinc-tin system remains uncertain. No data have been found for alloys with more than 30% tin, or more than 50% zinc. The work of Hansen^{1,2} and his collaborators has, however, elucidated the structure of the copper-rich alloys satisfactorily and this article is largely based on their work.

The constitution of any ternary system is, of course, related to the binary systems composing it, and it will be appreciated that the uncertainty in the copper-tin system (see article on page 1364 of this handbook) is present to an even greater extent in the ternary systems based upon it. The copper-zinc system is better established (page 1367 of this volume). The zinc-tin system has a eutectic at 9.0% zinc and 199°C. (page 1756 of this handbook). This eutectic is formed between zinc and tin, each with a very small amount of the other metal in solid solution. No other phases are present.

The liquidus surface (melting point) of the ternary system was first determined by Hoyt^{3,4} in 1913, who also described the microstructure of the alloys and outlined the alpha, beta and gamma fields. Prior to this Guillet⁵ had studied the structure of cast alloys in an attempt to determine a coefficient of equivalence for the substitution of tin in the brasses.

The work of Hudson and Jones⁶ established the alpha, beta, and gamma fields near the copper-zinc side of the diagram of 425°C. Campbell⁷ determined the limits of the microstructural fields in the copper-rich alloys in the cast condition and after annealing at 650°C.

X-ray studies of the parameter and limit of existence of the alpha phase in the ternary system have been made by Konobejewski, Tarassowa and Stepanova.⁸

Tammann and Hansen¹ in 1924 reported the results of thermal studies and a limited amount of microscopic work on the basis of which they drew a diagram above 50% copper, omitting the area beyond the appearance of the gamma phase. This work forms the basis of Fig. 1, which shows the liquidus isothermals of the system. Tammann's and Hansen's lines have been displaced somewhat in the region from 50-70% copper and up to 10% tin, in which preference for the more detailed work of Bauer and Hansen⁹ has been given. This latter paper, which includes a critical review of all earlier work on the system, contains an accurate experimental study of the limited region from 50-70% copper and 0-6% tin.

Fig. 1—Liquidus isothermals of the copper-zinc-tin system.

Liquidus Surface—The melting point of copper is decreased by addition of either zinc or tin, or both. The sloping liquidus lines in the binary systems become a sloping surface in the ternary model. The isothermal lines of Fig. 1 represent the contours of this surface. The heavy line running from 61.5% copper and no tin to 25% tin with no zinc is the intersection of the peritectic surface with the liquidus; to the copper-rich side of this the alpha phase is the first to solidify from the melt, and on the other side, the beta phase. The second heavy line represents the other limit of the primary beta field, and is followed by gamma or uncertain phases related to those in the copper-tin system.

The solidus has not been well established. According to Tammann and Hansen, the peritectic horizontal of the copper-tin system continues as an almost horizontal surface across the ternary model at a temperature of about 800°C., but rapidly inclines and rises to join the copper-zinc peritectic at 905°C. in that range below about 10% tin. Practically, this means that a vertical section passing through the

*Deceased. †Research Metallurgist, The American Brass Co., Waterbury, Conn.

copper corner of the ternary diagram and thus representing a constant ratio of tin and zinc is almost identical with the copper-tin system with a distorted composition scale until the zinc exceeds over four times the tin content. The same applies to the solid phases and a eutectoid similar to that in the copper-tin system exists in alloy containing as little as 4% tin with 38% zinc. Of course, all horizontal lines in the binary systems become double, usually curved, and not necessarily horizontal in the ternary system, but the displacement in this part of the present system is very small.

Both the alpha and the beta phases in the two binary systems are isomorphous—that is, they have the same crystal structure and form an unbroken series of solid solutions with each other, in which zinc can be replaced by tin and vice versa without introducing new phases. In the copper-zinc system the beta phase is stable (except for a change to a disordered structure) at all temperatures up to the melting point, but the corresponding phase in the copper-tin system is unstable at temperatures below 520°C. and it is therefore impossible for the ternary beta phase to extend right across the diagram below this temperature. Actually the ternary beta phase continues to suffer eutectoidal decomposition at almost the same temperature as in the binary copper-tin system until within about 3% of the copper-zinc binary side, when the beta boundary rapidly falls to lower temperatures, forming stable beta.

The eutectoid line at 520°C. in the binary copper-tin diagram, on which beta is in equilibrium with both alpha and gamma, becomes, as it extends across the diagram, a narrow band in which all three phases can co-exist over a small temperature range. This spreads to cover a wide range of temperature underneath the beta phase just before the beta boundary descends near the zinc side of the diagram.

These facts are represented in Fig. 2 which is a horizontal section of the diagram at 500°C. This shows the maximum extension of the alpha phase, and is just below the temperature at which most of the ternary beta phase has undergone eutectoidal transformation to alpha plus gamma. A similar section at a temperature above 520°C. would show the beta phase extending right across the diagram in a band of width increasing with temperature up to the solidus, and the three phase zone of alpha plus beta plus gamma would disappear.

The alpha phase boundary in Fig. 2 is that shown by Konobejewski and his co-workers. This is based on lattice parameter determinations, assuming a plane Vegard surface, and, even though rather few alloys were used, is probably quite accurate. Konobejewski and Tarassowa¹ had previously shown that the alpha boundary in the copper-tin system fell to very low solubilities at low temperatures, and the same behavior was found in the ternary system. Konobejewski and Tarassowa¹ even found a slight decrease in solubility (down to 33.3% zinc at 167°C.) in the much studied copper-zinc series. The dotted line in Fig. 2 shows their results for the ternary system at 300°C. It should be pointed out, however, that although this line represents equilibrium conditions, reactions at these temperatures are so very sluggish that for all practical purposes the solubility should be considered as that shown at 500°C.—unless indeed the good elastic properties of the tin bronzes at room temperatures are due to their inherent instability.

The delineation of the gamma field is difficult. Although gamma copper-zinc and delta copper-tin, both with an electron-atom ratio of 1.62, have the same type of cubic crystal structure and therefore could be isomorphous, they do not seem to form an unbroken series of solid solutions with each other. Beyond this little can be said. Delta copper-tin is unstable below 380°C. and the stable phases over part of the ternary diagram at low temperatures, must, therefore, be alpha plus epsilon copper-tin or a phase derived from it by substitution of zinc for some tin

Fig. 2—Horizontal section of the copper-zinc-tin constitution diagram at 500°C.

atoms. In the zone rich in tin in Fig. 2 the phase labeled gamma may be gamma, delta, both, or perhaps neither.

Fig. 3—Portion of diagram of copper-zinc-tin alloys of most importance.

Fig. 4—Vertical section of copper-zinc-tin alloys containing 1% tin.

Because of the industrial importance of alloys of the alpha beta brass type containing small additions of tin, that part of the diagram relating to these is reproduced in a larger scale in Fig. 3 taken directly from the work of Bauer and Hansen,² and representing their results at 400°C., the lowest temperature at which changes can occur rapidly enough to be of practical importance. It is interesting to note that the solubility of tin in zinc saturated alpha at this temperature is only 0.4% but beta contains 1.5% tin at saturation. Fig. 4, also from Bauer and Hansen, is a vertical section of the ternary model on a plane containing one per cent tin, parallel to the copper-zinc face.

The Physical Constants of Copper

By Cyril Stanley Smith*

Atomic weight	63.57
Atomic volume	7.11
Crystal structure, 20°C.	Face-centered-cubic, $A_0 = 3.6078 \text{ \AA}$
Density, 20°C.	8.94 g. per cc.
Density, 1083°C. (solid)	8.32 g. per cc.
Density, 1083°C. (liquid)	7.93 g. per cc.
Melting point	1083.0°C. (1981.4°F.)
Boiling point	2325°C. (4217°F.)
Specific heat, 25°C.	0.0918 cal. per g. per °C.
Latent heat of fusion	50.6 cal. per g.
Linear coefficient of expansion, 20°C.	16.42×10^{-6} per °C.
Electrical resistivity, 20°C.	1.682 microhms (cm.)
Electrical conductivity, 20°C.	0.594 megmho (cm.)
Thermal conductivity, 20°C.	0.923 cal./cm. ² /cm./sec./°C.
Magnetic susceptibility	-0.085×10^{-6}
Electrochemical equivalent, Cu ⁺	0.32940 mg. per coulomb
Cu ²⁺	0.65880 mg. per coulomb
Viscosity, 1145°C.	0.0341 cgs. units
Surface tension, 1150°C.	1104 dynes per cm.
Reflectivity, $\lambda = 6500 \text{ \AA}$.	80%
$\lambda = 4500 \text{ \AA}$.	37%

The atomic weight figure is from the 1939 table of International Atomic Weights, as published by the American Chemical Society. The figures for the remaining properties have been selected from various sources and need a little discussion to indicate their probable accuracy. Where no references are given the values were obtained in the laboratories of the American Brass Co.

Melting Point—The melting point of copper is used as a secondary standard of temperature, the accepted value being 1083°C. Roeser^a showed that on the 1927 International temperature scale the melting point of copper as determined by thermoelectric measurements is $20^\circ \pm 0.1^\circ\text{C}$. above that of gold, the primary standard at 1063°C. Any change in the value assigned to gold on the thermodynamic scale will apply equally to copper.

Fig. 1—Vapor pressure of copper.

+ = Greenwood²; x = Ruff and Bergdahl³; o = Ruff and Könschek⁴.

Crystal Structure—Copper is face-centered cubic in structure. By measurements of reflections from planes of high indices and by the use of 11 different characteristic

*Research Laboratory, The American Brass Co., Waterbury, Conn.

wave lengths (assuming the I.C.T. values for these) Owen and Iball⁴ obtained the value 3.6076 ± 0.0003 Å at 16.5°C . Corrected to 20°C , this becomes 3.6078 Å, in exact agreement with the value independently obtained by the precision method of Kaiser and Barrett,⁴ 3.6078 ± 0.0001 Å. Owen and Yates, as a result of further careful study, give the value at 18°C . as 3.6077 ± 0.0002 Å. This becomes 3.6078, when corrected to 20°C . Wever and Lohrmann⁴ studied the corrections to be applied to the Debye method and gave a most probable value of 3.608 ± 0.001 Å. Ageew, Hansen and Sachs⁴ and Wiest⁴ used planes giving a high angle of diffraction, and obtained values of 3.6081 and 3.6085 ± 0.002 Å respectively. The agreement between all the recent values is remarkably good.

Density—The standard value adopted by the International Electrotechnical Commission in 1913 was 8.89 g. per cc. at 20°C ., which is the value used in all conversions of mass to volume conductivity. This figure is approximately correct for commercial copper, but is too low for copper containing no oxygen. Many years ago this laboratory found that the density at 20°C . of commercial annealed copper in which the principal impurity was oxygen existing in the form of Cu_2O could be expressed approximately by the relation

$$d = 8.933 - 0.44 (100 - \% \text{ Cu}) \text{ g. per cc.}$$

The density of pure copper is certainly as high as 8.94, which is the value required by the crystal structure. Maier⁴ gives a figure for the density of a single crystal as 8.953, and supposedly reliable figures as high as 9.0 g. per cc. have been reported for certain types of deoxidized copper solidified under unusual conditions. Lacking further evidence the figure 8.94 will be accepted as representative of the density of annealed pure copper. Cold working will decrease this value by a maximum of 0.1%. Castings of ordinary deoxidized copper will have a density of 8.8 to somewhat over 8.9. Tough-pitch copper will be much lower than this, but rarely below 8.4.

Bornemann and Sauerwald⁷ give the density of solid copper at the melting point as 8.32 g. per cc. The density of liquid copper at the melting point is 7.93 g. per cc., according to Widawski and Sauerwald⁸ who studied the density by a displacement method. Above the melting point the density increases linearly with temperature until at 1600°C . it is 7.53 g. per cc.

Boiling Point, Vapor Pressure—The vapor pressure of copper at high temperatures has been studied by several observers^{2, 3, 4, 9} whose results are summarized in Fig. 1. The average value for the boiling point at 760 mm. pressure is 2325°C . At lower temperatures the results of the various observers differ considerably and the curve can be regarded as only an approximation. Other data not shown in Fig. 1 are those of Ruff and Mugdan⁴ which agree with those of Ruff's other collaborators, and Bauer and Brummer⁴ whose results, in the range 1500 – 1850°C ., lie somewhat higher than those in Fig. 1. Hardeck⁴ and Marshall, Dornste and Norton⁴ among others have determined the vapor pressure from measurements of the rate of evaporation at temperatures below 1300°C ., where the pressure is of the order of 10^{-4} cm.

Specific Heat—In spite of the large number of investigators who have determined the specific heat of copper it is by no means easy to select a precise figure. At temperatures below atmospheric the results of Nernst,¹⁰ Eucken & Werth,⁴ Dockerty,¹¹ Kok and Keesom, Keesom and Onnes, all agree almost exactly in the range where they overlap and the curve shown in Fig. 2 is drawn through their results which are indistinguishable at the scale of plotting.

Agreement above room temperature is as poor as agreement of the low temperature results is good. No single investigation seems to be reliable for the range between 0 and 1083°C . The most probable curve, drawn in Fig. 3, passes closely through results of Bronson, Chisholm and Dockerty,¹² Seekamp¹³ and Schubel,¹³ up to about 300°C . and above this point follows Jaeger, Rosenbohm and Bottema, whose results above 600°C . are closely checked by Esser, Averdick and Grass.¹⁴ The specific heat of copper in the liquid state is given by Esser, Averdick and Grass as 0.11 cal. per g. per $^\circ\text{C}$. Umino reports 0.12 while Wüst,

Fig. 2—Specific heat of copper at low temperatures.

Meuthen and Durrer consider the specific heat to vary from 1.0-1.3 cal. per g. per °C. between 1110 and 1300°C. Esser's figure, the most recent, has been used in constructing Fig. 2 and 3.

The precise measurements of Griffiths and Griffiths¹ and Harper⁴ in the neighborhood of room temperature agree with the curve shown in Fig. 3. The average value of Bronson and his collaborators,¹¹ Dockerty,¹² Griffiths and Griffiths,¹ and Harper⁴ at 25°C. is 0.0918 cal. per g. per °C. which is adopted for the table of data.

Latent Heat and Heat Content—Wüst and his collaborators¹ give 40.97 cal. per g. as the latent heat of fusion of copper. This is evidently a typographical error for their tabulated experimental data show a difference of 50.97 cal. per g. between the heat contents in the solid and liquid states at the melting point. This revised figure agrees with that of Umino (49.94) and Esser, Averdick and Grass (50.9). The average of these three values, 50.6 cal. per g., is probably very near the true one.

Fig. 3—Specific heat of copper at high temperatures.

Fig. 4—Heat content of copper.

The heat content curve, Fig. 4, is not taken directly from any experimental work but is calculated on the basis of Fig. 3 and the above latent heat. The curve is believed to be more accurate than any single published work, for those who have studied the high temperature heat content have usually extrapolated to room temperatures with too high results for the specific heat. Although Umino⁹ and Wüst, Meuthen & Durrer⁸ are frequently quoted, their results are not in close agreement either with each other or with other data. Esser's curve agrees closely with Fig. 3 although the derived specific heat values at low temperatures are too high.

Linear Coefficient of Expansion—The linear coefficient of expansion of a hot rolled rod containing 99.968% copper has been determined by Hidnert,¹¹ who gave the following equation to represent his results between 16 and 300°C.:

$$L_t = L_0 (1 + 0.00001623t + 0.00000000483t^2).$$

This corresponds to a value of the instantaneous expansion coefficient at 20°C. of 0.00001642, which value is adopted as the most probable.

Uffelmann's¹⁰ results are not greatly different from these, Eucken and Dannohl¹⁰ determined the coefficient up to 825°C. and gave an equation from which the values in the following table were calculated.

Wilson and Davey¹³ give the total expansion between 27 and 1083°C. as 0.0260 cm. per cm., corresponding to an average coefficient of 24.62×10^{-6} . The total expansion from absolute zero to the melting point was found by Haring and Davey¹⁴ to be 3.01% of the length at 0°K.

Linear Coefficient of Expansion of Copper^a

Temp., °C.	Linear Coefficient of Expansion × 10 ⁻⁶ , per °C.	
	Average (0°C.-T)	Instantaneous
0	15.89	15.89
20	15.97	16.07
25	16.00	16.12
50	16.12	16.37
100	16.37	16.90
200	16.93	18.16
300	17.58	19.64
400	18.30	21.35
500	19.10	23.29
600	19.98	25.48
700	20.94	27.89
800	21.96	30.54

Cold working may increase the coefficient of thermal expansion by as much as 2%.²²

The coefficient at low temperatures has been studied by Dorsey,¹³ Keesom,²³ and Buffington and Latimer.¹⁴ A smooth curve drawn through their results gives the following approximate average values of the instantaneous temperature coefficient:

°C.	Temp. °K.	Instantaneous Coefficient of Expansion × 10 ⁻⁶	°C.	Temp. °K.	Instantaneous Coefficient of Expansion × 10 ⁻⁶
-223	50	4.4	-123	150	13.4
-198	75	7.7	-73	200	15.0
-173	100	10.1	-23	250	16.0

Electrical Resistivity—The International Annealed Copper Standard, adopted in 1913 to represent the average of high grade commercial conductivity copper, has a resistance of 0.15328 ohm (m. g.) at 20°C. This is equivalent to a resistivity of 1.7241 microhm (cm.), and a conductivity of 0.5800 megmho (cm.).

Occasional values for the mass conductivity as high as 102.8% International Annealed Copper Standard have been reported. However, the highest value obtained by The American Brass Co. on a large number of samples of annealed commercial copper since 1921 is 101.90%. Absolutely pure copper would probably have a conductivity about 1% higher, but this value has been accepted in the present tables since it represents the highest authentic determination. Using 8.94 g. per cc. as the density, this is equivalent to a volume conductivity of 0.5943 megmho (cm.), or resistivity of 1.682 microhm (cm.). If the standard value of 8.89 is used for the density the conductivity is 0.5910 megmho (cm.), but for the reasons stated above pure copper undoubtedly has a density higher than this.

The International Standard value for the constant mass temperature coefficient of resistivity is 0.00393 per °C. at 20°C. Burgess¹⁶ made an accurate determination of the coefficient between 0 and 150°C. and gave the following equation:

$$R_t = R_0 (1 + 0.0041151t - 0.0000019988t^2).$$

The resistivity of copper at high temperatures has been determined by both Northrup¹⁷ and Tsutsumi,¹⁸ whose results agree well. Northrup's results are reproduced in Fig. 5.

The electrical resistance of single crystals of copper seems to be little different from polycrystalline material of equal purity.^(21, 20, 21)

Thermal Conductivity—Lees¹⁹ gives the thermal conductivity of copper at 25°C. as 0.915 cal. per sq. cm. per cm. per sec. per °C. Schofield²⁰ determined the conductivity of a sample of copper with 99.6% electrical conductivity. Interpolation of his results gives the values in the table on the next page.

Smith,²¹ working with very pure copper of 101.66% electrical conductivity, obtained the value of 0.941 ± 0.005 cal. per sq. cm. per cm. per sec. per °C. at 20°C., the temperature coefficient being -0.000041 . This value for the temperature coefficient is probably too low. A carefully weighted mean of all the results published since 1900 is 0.9225 cal. per sq. cm. per sec. per °C., and the corresponding average

electrical conductivity is 99.6% International Annealed Copper Standard. This is the value given in the present table, although very pure copper would certainly have a conductivity about 2% higher than this.

Fig. 5—Effect of temperature on electrical resistivity of copper (Northrup).

Temp., °C.	Thermal Conductivity		Temp., °C.	Thermal Conductivity	
	cal/cm ² /cm/sec/°C.	Watts/cm ² /cm/°C.		cal/cm ² /cm/sec/°C.	Watts/cm ² /cm/°C.
0	0.912	3.82	300	0.879	3.68
20	0.910	3.81	400	0.867	3.63
100	0.901	3.77	500	0.856	3.58
200	0.890	3.72	600	0.845	3.45

Angell²¹ gives the conductivity at 1000°C. as 0.80 cal. per sq. cm. per cm. per sec. per °C. Grüneisen and Goens²² give the conductivity at -190 and -250°C. as 1.33 and 21 cal. per sq. cm. per cm. per sec. per °C. respectively.

The thermal conductivity of single crystals of copper is somewhat higher than polycrystalline material, although the electrical conductivity is approximately the same. Kannaluik and Laby²³ obtained the value 0.989 cal. per cm.² per sec. per °C. at 19.4°C. for a single crystal grown by the Bridgman method.

The ratio between thermal conductivity and the product of electrical conductivity and the absolute temperature is approximately constant.

Magnetic Properties—Honda²⁴ and Owen²⁵ have determined the susceptibility of copper containing 0.008 and 0.0004% iron, the values being -0.086×10^{-6} , and -0.085×10^{-6} respectively. Endo²⁶ gives the susceptibility of solid copper at 1080°C. as -0.077×10^{-6} and liquid copper at 1090° as -0.054×10^{-6} . The susceptibility of a sample of copper measured by Haas and VanAlpen increased from -0.086×10^{-6} at 6°C. to -0.097×10^{-6} at 14 to 20°K. (-259° to -253°C.).

Watase²⁷ found the diamagnetic susceptibility of copper to be increased by elastic stress. The susceptibility also increases with decreasing particle size, the effect becoming very marked below an average diameter of 1 μ , according to the work of Rao.²⁸

Bitter²⁹ found the susceptibility of an impure paramagnetic sample of copper to increase when stretched, although annealing restored the original value. Honda and Shimizu³⁰ found a change from the diamagnetic to the paramagnetic state (susceptibility -0.083×10^{-6} to $+0.06 \times 10^{-6}$) when the samples were compressed, and a return to the original value on annealing at 250°C. or above. Banta³¹ failed to confirm this change, but later work of Lowance and Constant³² and Kussmann and Seemann³³ proved without doubt that the change was real. Kussmann and Seemann suggested that it was due to the precipitation of iron due to cold work, for the solubility of iron in copper at room temperatures³⁴ is of the order of 6×10^{-11} . They found the susceptibility after cold working to be dependent on the iron content even in the small amounts present in commercially pure copper (about 0.0001%). The susceptibility of annealed material is independent of field strength but after cold work it decreases as the field strength is increased. Shimizu³⁵ showed that copper actually becomes more diamagnetic on cold working if the values of the susceptibility are extrapolated to infinite field strength to eliminate the effect of ferromagnetic impurities. There is little doubt that Kussmann and Seemann's pre-

precipitation theory is correct, but it is probable that the effect will be partly dependent on the prior treatment of the copper.

Single crystals of copper are magnetically isotropic (Montgomery²⁰).

Electrochemical Equivalent—Taking 63.57 and 107.880 as the atomic weights of copper and silver respectively, and 1.118 mg. per coulomb as the equivalent of silver, the electrochemical equivalent is 0.3294 mg. per coulomb for bivalent (cupric) copper and 0.6588 mg. per coulomb for monovalent (cuprous) copper.

Viscosity—Bienias and Sauerwald²¹ determined the viscosity coefficient of molten copper by observing the rate of flow through a capillary tube. At 1145°C. the coefficient is 0.0341, and at 1189°C., 0.0329 cgs. units. The results do not vary uniformly with temperature and are probably accurate only to within ± 0.002 units.

Surface Tension—Smith,²² Libman,²³ and Drath and Sauerwald²⁴ give values for the capillary constant (mm²) at 1150°C. of 28.8, 30.8 and 28.81 respectively. Using Widawski and Sauerwald's value for the density (7.89 at 1150°C.), these values correspond to a surface tension of 1113, 1190, and 1113 dynes per cm. Krause and Sauerwald²⁵ give the following values:

Temp., °C.	Surface Tension Dynes per cm.	Capillary Constant (mm ²)	Temp., °C.	Surface Tension Dynes per cm.	Capillary Constant (mm ²)
1140	1120	28.35	1280	1193	30.83
1150	(1127)	(28.58)	1500	1226	32.01
1200	1160	29.70	1335	1251	32.84

The temperature coefficient of the surface tension is given as +0.66 which is remarkable both for its high value and because it is positive. Libman does not confirm this. Krause and Sauerwald seem to have used a very high density (8.04 at 1150°C.) in converting their experimental capillary constant values to surface tension, and if Widawski and Sauerwald's value is used, the surface tension becomes 1104 dynes per cm. at 1150°C., which is probably not far from the correct value.

Fig. 6—Reflectivity of polished copper (Hagen and Rubens).

Optical Properties—The optical properties of polished copper have been studied by Hagen and Rubens,²⁶ Tool²⁷ and Tate.²⁸ Some of Hagen and Rubens' values for the reflectivity are reproduced in Fig. 6. The sharp increase in reflectivity at 5700 Å., responsible for the red color of the metal, will be noticed.

The relative emissivity of solid and liquid copper was determined by Stubbs²⁹ who obtained the following results:

Wave Length, Å	Solid, 1000 °C.	Emissivity % Liquid, 1125 °C.	Wave Length, Å	Solid, 1000 °C.	Emissivity % Liquid, 1125 °C.
7000	8.7	11.8	5500	31.3	29.3
6500	11.2	14.8	5000	40.4	38.7
6000	18.5	20.5			

These results agree well with those of Burgess,³⁴ and with the values calculated from the reflectivity figures.

Mechanical Properties—Although commercial copper regularly contains over 99.9% copper, it is very difficult to give definite values for the tensile properties of absolutely pure copper, since even minute amounts of impurities have considerable effect. Hanson, Marryat and Ford²² give the following figures for rolled and annealed copper rod, % in. dia., containing 0.015% oxygen and about 0.005% iron as the sole detectable impurities.

Tensile strength.....	31,790 psi.
Elongation ($L = 4\sqrt{A}$).....	58.0%
Reduction of area.....	72.8%

The tensile strength of copper varies considerably not only with the composition but also with the mechanical and thermal treatment to which it has been subjected. This is described in more detail in the article on Commercial Copper in this Handbook.

Large crystals of copper may be grown by a process of critical straining and annealing, or even by hot rolling under suitable conditions of temperature, rate and amount of reduction, but such crystals are always heavily twinned and are not suitable for the study of the properties of single crystals. By progressive solidification from the molten state untwinned crystals of copper are obtainable and the mechanical properties of these have been studied by Elam²³ and by Güler and Sachs.²⁴ According to the latter workers, the yield point in tension depends on the orientation of the crystal in relation to the stress but corresponds to a definite shear stress of about 570 psi. on the 111 plane most favorably placed for slip. Slip is confined to this plane until the crystal has rotated sufficiently to bring another 111 plane to make an equal angle with the direction of stress, when slip proceeds along both planes simultaneously, the crystal orienting itself with the 121 axis parallel to the direction of the stress.

Properties of Commercially Pure Copper

By H. C. Jennison† and Cyril Stanley Smith*

In the article on the Physical Constants of Copper, page 1380, are given the properties of the substantially pure element. Many of the figures were actually determined on good grades of commercial copper, which is always of high purity except for the presence of oxygen and does not differ greatly in many of its properties from absolutely pure copper. The present article discusses the various grades and forms of commercial copper and their mechanical properties, together with the influence of the various impurities or intentional additions that are often encountered and the effect of such mechanical and heat treatments as are customarily given.

Grades and Composition—The principal grades of copper at present in use in the United States are Electrolytic, Lake, Lake Arsenical, Casting, Deoxidized, and various forms of oxygen free copper. By far the greatest amount of copper used in this country is electrolytic. In England an additional grade known as "Best Select" is used for many purposes. Both the American Casting copper and the English Best Select are fire refined and contain more impurities than the electrolytic grades. Statistics regarding the production of the various grades of copper are given in the article on Copper Industry, page 1339, and are annually published by the American Bureau of Metals Statistics.

Typical compositions of some of the principal grades of copper are given in Table I.

*American Brass Co. analyses.

†Analyses given by Lovell and Kenny*.

‡Analysis given by Webster, Christie, and Pratt*.

Electrolytic Copper—Electrolytic copper, as its name implies, is produced by electrolysis from relatively impure fire refined anodes or deposited directly from a solution containing copper leached from the ore. About 23% of the cathodes produced are sold as such and are used in the manufacture of copper alloys, but the greater proportion of the electrolytic copper of commerce is remelted or "refined". The latter process comprises the well known operations of oxidation to remove sulphur and other elements adsorbed on the cathodes or absorbed during melting and poling with green wood poles, which reduces the oxygen content to the correct amount. By electrically melting cathodes under proper conditions it is possible to avoid contamination by sulphur or gases and to pour tough pitch copper directly with no delay due to flapping and poling operations. This process has been made continuous. Electrolysis is necessary in the production of high purity copper only in the presence of objectionable impurities in the ores which cannot be removed by fire refining, or when, as is frequently the case, the extraction of precious metals contained in the blister copper more than pays for the cost of electrolytic separation. Much copper that is equal in quality to electrolytic metal is made from high grade ores entirely by fire refining operations.

†Deceased. *Research Metallurgist, American Brass Co., Waterbury, Conn.

Wire bar or ingot copper contains from 0.01-0.07% oxygen, usually about 0.04%. It is usual to judge the quality of tough pitch copper by the appearance of the "set surface" (the top surface of the casting exposed to the air during solidification), and an important part of the art of the refiner lies in balancing the oxygen and gas contents of the metal so that the gas liberated by reaction during solidification exactly balances the normal shrinkage which would occur due to the difference in density between liquid and solid copper. The correct set of tough pitch copper is approximately level with shallow wavy furrows regularly spaced over the surface. Copper with a rough convex surface is "overpoled" which indicates usually too little oxygen and always too much gas or sulphur. A concave, depressed, surface results from a high oxygen content under normal conditions of pouring. The set surface is modified by the dimensions and shape of the casting.

The density of cast tough pitch copper is 8.4-8.7 g. per cc. depending on the shape of the casting and the proportion of set surface. This density corresponds to the presence of about 3-5% of voids or gas holes, which in properly refined copper are small and distributed uniformly throughout the cross section of the casting. They are completely closed up during rolling. After working and annealing to produce maximum density, copper containing about 0.03% oxygen has a density of about 8.92, but this depends on the oxygen content.

Lake Copper—Lake copper, which constitutes about 10-15% of the United States output, derives its name from its origin in the Lake Superior region. It is not electrolytically refined, but is of high purity and if free from arsenic has an electrical conductivity equal to that of electrolytic copper. It differs from electrolytic copper in that it may contain small amounts of silver or arsenic. When arsenic is desired it may vary from 0.04-0.3% or even higher to suit the purpose for which the copper is intended. Arsenical and argentiferous coppers are not infrequently made synthetically from electrolytic copper.

Deoxidized Copper—Deoxidized copper is made by adding a strong reducing agent such as phosphorus or silicon to molten tough pitch copper, either to a ladle of metal removed from the refining furnace or to a crucible charge of remelted copper. The function of the reducing agent is to remove the residual oxygen present in all tough pitch copper. Deoxidized copper always shrinks deeply, forming a "pipe" that must be discarded or eliminated by feeding with molten metal. It should have a density of 8.8-8.9 g. per cc. or higher.

Deoxidized copper usually has a comparatively low electrical conductivity on account of residual amounts of the deoxidizing element. When a high conductivity is required, calcium,³ lithium,⁴ calcium boride or beryllium is sometimes employed as a deoxidizer. A commercial grade of phosphorized copper is available, made under controlled conditions so that the residual phosphorus content is below 0.005% and the conductivity will meet A.S.T.M. specifications for high conductivity copper, although it is fully deoxidized.

Oxygen-Free Copper—Oxygen-free copper is a commercially pure copper made by casting under conditions which prevent absorption of oxygen. Its conductivity is equal to that of

Fig. 1—Characteristic drawing curves of tough pitch copper.

tough pitch copper. A process has recently been introduced for continuous casting in which copper is withdrawn through a die and more molten metal introduced at the same rate that it solidifies. It is reported that the directional solidification results in unusually high density. Another new variety of oxygen-free copper is made by compressing broken brittle cathodes in a reducing atmosphere when hot and extruding them to bars without melting. All these methods have for their object the conversion of the copper cathodes with a minimum of contamination into a form fit for further work.

Both deoxidized and oxygen-free copper are used for applications where the presence of oxygen is harmful, as for example when a copper of exceptionally high ductility is required, when the copper is to be welded, or when it has to be heated in a reducing atmosphere. The absence of oxygen increases ductility particularly as

enhances the capacity for undergoing severe cold working operations. The hot ductility of tough pitch copper decreases to a minimum at temperatures ranging about 500°C. but in phosphorized copper this is much less marked.*

Gassing of Copper—When copper containing oxygen is heated for a sufficient time in a reducing atmosphere at temperatures above about 400°C. it becomes severely embrittled. Deoxidized or oxygen-free copper is not embrittled under the same conditions. This effect, which was first adequately described by Dick²⁰ in 1856, is due²¹ to the reaction between copper oxide and the reducing gases, which diffuse into the solid copper more rapidly than the gaseous reaction products can escape. The local high pressures developed actually blow the copper apart at the weakest points, which, at the temperatures considered, are the grain boundaries. A very slightly reducing atmosphere will cause trouble, as for example that resulting from traces of oil or even from the presence of steel on heating in a closed space. Such embrittlement never occurs during the fabrication of copper under proper conditions but is sometimes encountered when copper is employed in locations where a reducing atmosphere is unavoidable. In this case, deoxidized or oxygen-free copper should be employed, but it should be noted that when either deoxidized or oxygen-free copper is heated in an oxidizing atmosphere diffusion of oxygen will occur with the effective removal of the deoxidant in the surface layer and it is therefore important to avoid prolonged alternate treatment in oxidizing and reducing gases. Copper deoxidized in different ways differs considerably in its susceptibility to embrittlement by such treatments.*

Forms of Commercial Copper—Copper for remelting or alloying is sold in the form of cathodes, ingots, or "warmer bars". Commercial copper for rolling, with which this article is primarily concerned, is cast in the refinery in the form of wire bars, cakes, slabs, and billets of well defined standard shapes and weights. These castings are usually made directly from the refining furnace on a casting machine and are made in open molds of copper with the surface of the metal exposed to the air.

Wire bars for rolling to rod and drawing to wire customarily weigh 200-300 lb., although larger and smaller sizes are frequently cast. A 300 lb. bar is 54 in. long, 4½ in. high and tapers from 4 in. wide at the bottom to 4½ in. wide at the top. Both ends of the bar are usually pointed to facilitate rolling. The bars are cast horizontally and the top surface is exposed to the air during casting. Sometimes the oxidized set surface is removed by milling, or a special vertically cast wire bar with the set surface on the end may be used.

Cakes and slabs are used principally for rolling to sheet. They are approximately rectangular in section and of various shapes and sizes according to the product being rolled. In many cases they are poured on edge ("wedge cakes") or on end so that the set surface is on an unimportant part of the product being rolled, or may easily be trimmed off.

Billets are round bars cast on end. These may be from 2-10 in. dia. and vary in weight from 75-750 lb. They are used principally for piercing in the manufacture of seamless tubing and are usually of deoxidized copper. Some billets are used for extruding in the manufacture of rods and various shaped sections.

In addition to the cast shapes mentioned above and many special cast shapes, copper may be obtained for engineering uses in a wide range of semifabricated forms such as rod, bars, wires, tube, plate, and sheet, extruded and rolled sections of innumerable shapes and sizes.

Fig. 2—Effect of silver on annealing of copper (0.05 in. sheet). (Bassett and Davis.)

pose it is important that the furnace atmosphere be maintained neutral or oxidizing to avoid the action known as "gassing," which produces severe cracks in the surface.⁸

Sheet copper is sometimes used as it comes from hot rolling, but it is more commonly employed after it has been cold worked to increase its hardness and tensile strength. The tensile strength of hot rolled or annealed copper is about 30,000-36,000 psi., but this can be increased to almost 70,000 psi. by extensive cold working; this, however, is at the expense of some ductility.

Fig. 1, taken from the paper by Webster, Christie, and Pratt,¹¹ shows the variation of the tensile properties of tough pitch copper as it is cold worked to an increasing extent. The tests were made on wires drawn from 0.5 in. to successively decreasing diameters and show clearly the hardening effect due to cold working. Table II gives the A.S.T.M. specifications¹² for wire of different diameters and indicates the range of properties normally obtainable in commercial copper wire. It is not practical to perform extensive cold work on the larger sizes of wire, and for this reason the strength decreases as the section of the cold drawn wire increases. Cold rolling has a similar effect in increasing the strength and decreasing the ductility of copper sheet or strip.

The importance of several factors in affecting the change of properties during the cold working and annealing of copper has been studied by Mathewson and Thalheimer,⁹ Caeser and Gerner,¹⁰ Webster, Christie, and Pratt,^{11, 7} and others.

The increased hardness and strength due to cold work may be completely removed by annealing at a temperature above the "recrystallization temperature". This temperature is affected by the presence of even small amounts of impurities, particularly silver, antimony, and arsenic, and varies both with the amount of cold work which the copper has undergone and the length of the annealing operation. A curious fact is that in spite of its high purity the recrystallization temperature of "oxygen-free" copper is higher than ordinary electrolytic tough pitch copper.⁷

The different behavior on annealing of an electrolytic and a Lake copper with different silver contents is shown clearly in Fig. 2 (Bassett and Davis¹²). The two grades of copper are not greatly different in properties either in the worked condition or when fully annealed, but the temperature at which the rapid decrease in strength and increase in ductility occurs is different for the two grades.

Under extended periods of annealing perfectly pure copper will recrystallize at about 212°F., but the impurities in commercial copper usually prevent substantial softening at this temperature. In cases where slightly elevated temperatures are to be encountered in service and the superior properties due to cold working are desired, the importance of selecting a grade of copper with high recrystallization temperature will be obvious. The most common of such applications are for parts to be tinned or soldered, for engraver's plates, and, to some extent, for fire box plates and stays. For these purposes Lake copper or a natural or synthetic antimony or silver-bearing copper should be used.

Under normal conditions rolled copper will have small grain size (about 0.02-0.05 mm. dia.) and will not possess any marked directional properties due to a preferred orientation resulting either from cold working or from annealing. Under certain highly critical conditions of hot rolling large grains may form, and after extensive cold working considerable difference in properties in different directions may result. This becomes more pronounced on annealing at the high temperatures, but it is not a characteristic of correctly fabricated material.

Rolling—Copper is malleable at any temperature up to about 1050°C. The normal temperature for starting the hot rolling of copper for wire rod or sheet is about 850°C., and the finishing temperature may be as low as 400°C. The temperature of rolling is less important than that for other hot working processes, for example piercing or extruding, in both of which the temperature of the billets must be closely controlled. When heating tough pitch copper for rolling, annealing, or for any other purpose

After a careful study of all published values, Gillett¹⁴ concludes that the endurance limit of annealed commercial tough pitch copper rod is about 10,000 psi., as measured by the rotating beam test. Cold working increases this to values as high as 20,000 lb. Tests show that 15,000 psi. is a conservative value for commercial tough pitch copper in the cold drawn condition, but this will be changed by the presence of impurities.

Fig. 3—Effect of silver on annealing temperature of cold rolled copper sheet.

established in 1913 to represent the average of the best commercial material then being produced. Since that time refining methods have improved, and it is not at all unusual to find copper with a conductivity of over 101%, and occasionally as high as 102% of the standard. This standard corresponds to a resistance of 0.15328 ohm (m.g.) at 20°C., and the density is assumed to be 8.89 g. per cc. This is equivalent to a resistance of 1.7241 microhm-cm., or a conductivity of 58.0 ohms⁻¹ (m., mm.²) at 20°C. A.S.T.M. specifications for Electrolytic and Low Resistance Lake copper,^{1,2} call for a resistivity not exceeding 0.15436 ohm (m.g.) at 20°C., that is, a conductivity not less than 99.3% I.A.C.S.

The electrical resistance of copper increases with temperature, the constant mass coefficient at 20°C. being about 0.00393 per °C. At 100°C. the conductivity is thus only about 76% of the conductivity at 20°C. The temperature coefficient at 20°C. is approximately directly proportional to the actual value of the conductivity.

Severe cold working decreases the electrical conductivity about 3%, but the factor of greatest importance is the presence of impurities. As little as 0.02% phosphorus reduces the conductivity 20%, although 0.2% of oxygen reduces the conductivity only about 2%. The elements are approximately in the following order in their effects in small amounts^{15, 16, 17, 18}: Phosphorus, silicon, arsenic, iron, beryllium, manganese, aluminum, antimony, nickel, tin, zinc, gold, cadmium, sulphur, silver, oxygen, and lead. The effect of many of these elements depends on the amount of oxygen in the copper.

The thermal conductivity of copper, of electrical conductivity equal to 100%, International Annealed Copper Standard, is about 0.93 cal./cm.²/cm./sec./°C. The presence of impurities decreases the conductivity considerably but somewhat less rapidly in proportion than the electrical conductivity. The ratio between the two conductivities depends on the actual value of the conductivity, but is relatively independent of the composition.¹⁹

The Effect of Impurities on Copper—A detailed study of the effect of impurities on the mechanical and electrical properties of copper has been made by the British Nonferrous Metals Research Association.²¹ The results have been published on oxygen,²¹ iron,²² bismuth,²³ arsenic,²⁴ phosphorus,²⁵ and antimony.²⁶ An excellent summary of the properties of argentiferous and arsenical copper is given in the book by J. L. Gregg.²⁰

Oxygen²¹ is present in all commercial copper except in deoxidized and some other special grades. It exists in the casting as a copper-copper oxide eutectic and in worked copper in the form of small globules of Cu₂O, visible under the microscope. Its effect on the mechanical properties is not great, although it reduces the ductility as shown by the reduction of area in the tensile test, and slowly increases the tensile strength. The first additions of oxygen in commercial copper often have the effect of increasing the electrical conductivity, probably due to the partial oxidation of other impurities which are thereby removed from solid solution, but large amounts of oxygen slowly reduce the conductivity by reducing the effective cross section of metal.

Sulphur,^{22, 23} selenium,²² and tellurium²³ are generally regarded as being extremely harmful to copper but this is actually the case only in tough pitch copper, and possibly only sulphur is harmful there. Amounts up to about 1% of selenium and tellurium may be used for the purpose of promoting machinability without the hot shortness concomitant with lead. These elements exist in the form of eutectics

of copper with Cu_2S , Cu_2Se , or Cu_2Te similar to the copper oxide eutectic, and have a similar effect on the mechanical properties.

Bismuth² is almost completely insoluble in copper and promotes brittleness if in amounts over about 0.001%. The solubility of bismuth varies with temperature, and by quenching from a high temperature bismuth up to 0.006% may be rendered harmless in arsenical copper (Blazey³). Bismuth is rarely encountered in detectable amounts in American copper. Its effects may be partly neutralized by additions of suitable corrective elements, such as oxygen, arsenic, and antimony.¹

Antimony² is sometimes added to copper where a high recrystallization temperature is desired. In amounts of 0.5% and even higher it slightly hardens copper and decreases the ductility, but it cannot be considered a harmful impurity except where the highest conductivity is required. The presence of antimony is extremely harmful to brass, and antimony-bearing scrap copper is anathema in the brass mill.

Arsenic² occurs naturally in Lake copper and may be allowed to remain after refining in amounts up to 0.3% or higher. It is often added intentionally in amounts to 0.6%, particularly in European coppers. It has a small hardening and strengthening effect, especially in the cold worked condition, raises the recrystallization temperature, but is practically without effect on ductility. It decreases the conductivity considerably.

Silver is, after oxygen, the most common element that occurs in appreciable quantity in commercial copper. It has rather small effect on the mechanical properties and electrical conductivity, but has as great an effect on the recrystallization temperature as any element. The effect is clearly shown in Fig. 3, taken from the paper by Kenny and Craig.²

Iron² is normally present in copper only in small amounts which are totally without effect on the mechanical properties. Added in amounts up to 2% it hardens and strengthens copper slightly without destroying the ductility and reduces rapidly the electrical conductivity, particularly in the absence of oxygen, which lessens the effect. Copper and most of its alloys containing even traces of iron become feebly ferromagnetic on cold working, but annealing renders them nonmagnetic again.

Lead should be present in amounts not over 0.005% if copper is to be hot rolled, although in much larger amounts it has little effect on the ductility of copper at room temperatures. It can be rendered less harmful by the presence of oxygen.

Cadmium is rarely present in commercial copper, except when it is intentionally added in amounts of about 0.7-1.0% for the production of an alloy of high strength with good conductivity which finds extensive application for trolley wire. Strengths as high as 92,000 psi. with an electrical conductivity of 80% I.A.C.S. are readily obtainable in the cold drawn alloy.

Gases—The influence of gas in copper is a complex problem of greater importance to the producer of copper castings than to the user. The level set of tough pitch copper is believed by Allen² to be due to the liberation of H_2O or other insoluble gas by reaction as the oxygen concentration increases as the crystals progressively solidify. The amount of gas evolved should exactly neutralize the natural shrinkage of the metal on passing from the liquid to the solid state. Hydrogen is very soluble in liquid copper but will not cause unsoundness in copper castings in the absence of oxygen unless the solubility in the solid state, which is high, is exceeded. Carbon monoxide is probably soluble in solid and liquid copper to about the same extent and in the absence of oxygen is not harmful. Carbon dioxide and nitrogen both behave as if they were insoluble in copper.

Many other elements are intentionally added to copper for the formation of alloys. The elements listed above and those used as deoxidizers are practically all that are encountered in the various alloys which pass under the name of commercial copper and whose effects as impurities are important.

Properties of Copper-Zinc Alloys

(Commercial Brasses)

By D. K. Crampton*

The copper-zinc alloys, known as the brasses, form one of the most useful groups of alloys known to industry. These alloys are characterized by unusual ductility and malleability, good strength, excellent corrosion resistance, pleasing color, and other desirable properties. Many special or complex brasses, containing various alloying elements in addition to copper and zinc, are produced commercially, but the present article is confined to consideration of the common brasses, binary copper-zinc alloys.

The useful wrought alloys cover a wide range of composition, the copper content extending from about 55 to almost 100%. The range of properties is correspondingly great, making them suitable for a wide variety of uses. Fig. 1-6 and Table II give general properties for alloys ranging from about 60% to about 100% copper.

All the alloys may be cold worked, but some to a great degree. Alloys throughout the range may be hot worked, those with copper contents up to 65% and from 85-100% being capable of extensive hot working. Strength, for a given treatment, increases as copper content decreases.

Greenall and Gohn¹ have published data on fatigue or endurance properties of several brasses, which show that the endurance limit of 65-35 brass sheet increases from about 14,000 psi., annealed, to about 20,000 psi. as rolled 8 or 10 B & S numbers hard. Corresponding values for 72-28 brass are very slightly higher. Unpublished work indicates that the endurance limit of 85-15 brass (red brass) is still higher, the value for such material as rolled 8 B & S numbers hard being about 24,000 psi.

Toughness or impact strength for annealed material is quite generally high over the range of commercial alloys, increasing with zinc content to a maximum value at about 30% zinc and thereafter decreasing, the lowering of toughness becoming more pronounced with the appearance of the beta phase. The effect of cold working is to reduce toughness, this effect apparently being more severe in the alpha range of alloys than in the alpha plus beta range. These various points are illustrated in Table I.

Table I
Tensile Impact Values for 0.102 in. Wire
(Specimens 4.1 in. between grips)

Name	Composition, %		Temper	Tensile Impact Energy, ft. lb.
	Copper	Zinc

Cartridge or spinning brass.....	70	30	Annealed, drawn 60%	88
Muntz metal.....	59	41	Annealed, drawn 60%	13
				68
				28

The color is pleasing in all cases. Small percentages of zinc have practically no effect on the red copper color, but with 10% zinc a true bronze color is obtained. This merges into a red gold color at 20% zinc. With increasing zinc the color changes further, and 25-38% zinc produces the typical yellow brass color. From 38-45% zinc, the alloys take on a somewhat reddish cast.

The widespread use of the brasses is to a great extent due to their resistance to corrosion. The resistance of the entire range of alloys is good, but the optimum properties are probably found in the vicinity of 85% copper and 15% zinc.

All the alloys are machinable, although usually considered "tough" in machining, due to the tenacity of the chips. Machinability increases as the copper content decreases, the better machining alloys being those with from 55-63% copper. Where

really good machinability in desired, one of the several available lead-bearing brasses should be employed in preference to any listed here.

While brasses of all copper contents within the total range are useful ones, a few of definite composition have come to be standardized in commercial practice. These are usually referred to by generally recognized names and are to be preferred to slight modifications which do not increase their usefulness and only complicate production schedules. Table I outlines the names and compositions of the preferred alloys, their general properties, and typical uses.

Properties of Wrought Copper-Zinc Alloys (66-34 Brass)

By R. S. Pratt*

General—The copper-zinc alloys form ductile solid solutions with additions of zinc up to 36%¹ or with copper contents from 100-64%. With a zinc content of over 36% a second solid solution is formed which is appreciably less ductile in cold working. The 66-34 alloy is made commercially with a copper content between 64.5 and 67.5% and, therefore, represents about the lowest possible copper content in those alloys which contain simply the ductile alpha solid solution.² Because of this fact, the alloy has been well known as "common high brass" and is the cheapest alloy which is suitable for the more severe cold working, heading, cupping, forming, and spinning operations.

With the nominal 66-34 alloy, the second solid solution beta is never found except in the cast condition or in exceptional cases of severe overheating. When the copper content runs as low as 65%, however, the beta constituent is quite often found, particularly after a hot working operation has been used to break down the metal from the cast form. Proper annealing treatment will remove the beta constituent³ and it is, therefore, customary to regard the common high brass alloy as one purely of the alpha solid solution.

General Properties—The more general properties of the alloys are given in Table I.

The copper-zinc alloys are well known in general and there is much in the literature concerning them. There is, however, considerable confusion in many references as to the exact analysis, because many variations and types of alloys have been tested rather than concentrated work on a particular alloy.

Commercial Alloy of High Brass—The commercial limits quoted are of interest in understanding the comparatively wide range of alloys generally classified as high brass. Accepting these limits, the resulting range of properties due to variation in mixture is more or less apparent. For this reason, only the more important of the general physical properties are given in Table I.

Density—Hidnert⁴ gives some excellent data on the densities and coefficients of linear expansion of the copper-zinc alloys, including the 66-34 alloy. The density figure given in Table I checks the work of Bamford⁵ on a chilled cast alloy of the same mixture.

Table I
General Properties of High Brass

Commercial mixture limits, per cent.....	64.5-67.5 copper, 0.30 lead max., 0.07 iron max., zinc remainder
Melting range.....	1660-1715°F., 905-935°C.
Crystal structure.....	Face-centered cubic
Density at 20°C.....	8.47 g. per cm. ³
Weight per cu.in.....	0.306 lb.
Linear coefficient of expansion (25-300°C.).....	0.0000201 per °C.
Thermal conductivity at 20°C.....	0.286 cal. per sq.cm. per cm. per sec. per °C.
Specific heat at 18°C.....	0.0909 cal.
Electrical resistivity at 20°C.....	40.12 ohms per circular mil-ft., 6.68 microhms per cm. ²
Electrical conductivity at 20°C.....	25.85% (copper 100%)
Modulus of elasticity.....	15,000,000 psi.
Tensile strength—Annealed.....	40,000-50,000 psi.
Cold worked.....	50,000-140,000 psi.
Endurance Limit—Annealed.....	10,000-15,000 psi.
Cold worked.....	13,000-20,000 psi.

Coefficient of Expansion—The linear coefficient of expansion quoted covers the range between 25-300°C., but in Hidnert's⁴ paper it is given for each range of 100° between 25 and 300°C. It is interesting to note that these figures show an increasing coefficient with increasing temperature.

Thermal Conductivity—C. S. Smith⁶ gives the thermal conductivity of the copper-zinc alloys. In general, his values are higher over the range of alloys than those of the earlier workers on the same subject. Sedstrom⁷ gives a figure of 0.265

*Metallurgical Dept., Bridgeport Brass Co., Bridgeport, Conn.

cal. per sq.cm. per cm. per °C. per sec. for the 67-33 alloy, while Smith gives 0.288 cal. for a 65.5-34.5 alloy. Smith also reports a positive temperature coefficient of 0.001049 cal. per °C. at 20°C. for the latter alloy.

Specific Heat—Doerincel and Werner⁸ report a number of figures for specific heat of the copper-zinc alloys. A formula is given which is purported to give the specific heat at any temperature for a 67-33 alloy based on a straight line relationship between temperature and specific heat values. At the melting point, the specific heat may be computed to be about 0.11 cal. The value for specific heat at 0°C. is given in the Smithsonian Physical Tables as 0.0883.⁹

Electrical Resistivity—In the data sheet on copper alloys in Kent's Mechanical Engineers Handbook written by W. H. Bassett¹⁰ there is an excellent list of the resistivities of the whole series of copper-zinc alloys, apparently taken from determinations in his laboratory. The values quoted in Table I are taken from that table, although some determinations made in the author's laboratory show higher resistances. The International Critical Tables¹¹ report resistances of 6.302, 6.72 and 7.029 microhms per cu. cm. for alloys of this type as compared with the value of 6.68 microhms per cc. given in Table I.

Modulus of Elasticity—The data on modulus of elasticity for high brass are rather limited. Determinations made in the author's laboratory have shown a modulus of about 15,000,000 psi. with various samples and testing conditions. Townsend and Greenall¹² report a value of 14,500,000 psi. for this property.

Endurance Limit—The data on endurance limits of this alloy have been obtained from various sources. Dr. McAdam¹³ reported an endurance limit for annealed high brass slightly higher than for moderately cold worked material. The value for the annealed material was about 15,000 psi. and for the cold worked material from 13,000-17,000 psi. Townsend and Greenall¹² give 11,000 psi. as the endurance limit of annealed sheet brass and 13,000-15,000 psi. for rolled sheet brass.

Fig. 1—Effect of annealing temperatures on the properties of high brass.

Mechanical Properties—High brass, in common with most metals, hardens on cold working, which makes it necessary to anneal before further cold working may be done. The temperature and time of annealing are of primary importance in controlling the properties of the metal, and a knowledge of their effect is necessary in order to have an understanding of the properties which may be obtained.

When cast, the metal is fairly soft and ductile, but has a tensile strength and ductility appreciably lower than in the worked and annealed condition. The structure is not homogeneous, but contains some portions which are higher in zinc content than others and quite often it contains small amounts of porosity due to difficulties in the casting operation.

Annealing—The metal is annealed after casting to produce a homogeneous structure and is then cold rolled or drawn. In some cases it is possible to perform a

cold working operation before annealing which is advantageous in producing the homogenized structure. The metal may be hot worked if the impurities usually present are held to a minimum.¹⁴ When the metal hardens so that further cold rolling becomes impractical, it is then annealed to prepare it for further cold working. In annealing, the metal softens or recrystallizes at a temperature ranging from 475-650°F. (250-350°C.). The exact temperature depends on the amount of cold working prior to the annealing and the degree of annealing prior to the cold working operation.¹⁵

Fig. 2—Effect of cold drawing on the physical properties of high brass.

ber of investigators have reported a slight rise in tensile strength at temperatures below the recrystallization range,¹⁶ but it has not been possible to produce metal commercially so as to take advantage of this fact. These points are brought out graphically in Fig. 1.

Effect of Annealing Time—Considerable work has been done on the effect of time in annealing which would indicate that increasing the time will tend to soften the metal the same as does increasing temperature, although not to so marked a degree. This problem is brought out commercially in some types of electric annealing where a short time at high temperatures takes the place of lower temperatures for much longer periods of time. Commercially, the time element in annealing includes the time required to attain the desired temperature. In such cases, the time is of importance inasmuch as it indicates whether or not the metal has attained the desired temperature.

Effect of Cold Working—When the metal is fully annealed, it is ready for additional cold working and it is interesting to note the effect of various amounts of cold working. The first result is an increase in the tensile strength of the material and a very marked decrease in its elongation^{17, 18} with a somewhat slighter decrease in reduction of area. The rate at which reduction of area decreases with the amount of cold rolling or drawing is an excellent comparative indication of the ability of the metal to withstand successive cold working operations without failure.¹⁹ Emphasis is laid on the term comparative as, for example, the curve in Fig. 2 showing the effect of cold working might indicate that high brass is fairly ductile and capable of withstanding repeated cold working operations up to a reduction of about 70%. As a matter of fact, this figure may or may not be attained as it depends upon the method of working and the suitability of the tools used.

Effect of Impurities—High brass is made in several grades in which the difference is largely one of amount of impurities and this is controlled primarily by the purity of the zinc used. Lead and iron are the most common impurities so introduced, but occasionally small amounts of tin get into the mixture through the use

In this annealing temperature range, the tensile strength of the cold worked metal decreases to about 50,000 psi. and there is a notable increase in elongation and reduction of area. Annealing at higher temperatures results in a relatively slight further decrease in the tensile strength and is also accompanied by a more noticeable increase in elongation and reduction of area. There is also an increase in grain size with increasing annealing temperature from the minimum, which occurs immediately after complete recrystallization. A num-

of scrap containing tin. The higher grade alloys for eyelet brass and rivet wire use high grade zinc and the lead and iron contents are kept as low as 0.05% or even lower.

The effect of lead in quantities less than 0.10% does not seem to be apparent in the usual physical test data, but commercial experience would indicate that it is injurious if present in material which is required to withstand the most severe cold working operations. Lead in quantities over 0.25% has been found to aid materially when it is desired to machine articles made of high brass. Its function in this way is to break up the chips making their removal much less difficult. As the lead content is increased, the cold working becomes more difficult due to the decrease in percentage elongation and reduction of area. By compromising between the machining properties and ductility, it is possible to produce a number of valuable alloys merely by varying the lead content.

The effect of iron is much more noticeable for an equal quantity of impurity and amounts of over 0.05% decrease the grain size and increase the tensile strength appreciably. Because of this, most specifications limit the iron content to a maximum of 0.05%.

Use of High Brass—From Fig. 1 and 2, it may be seen that the properties which can be obtained in high brass cover a wide range. This accounts for the large number of uses to which it has been applied. Of all the materials used in the various fabricating plants, high brass is probably the most convenient to work with and the most simple to handle.

Large quantities of brass sheet are fabricated into a variety of articles such as electrical fittings, flashlight parts, and automobile hardware. Many of the articles are ornamental in character. High brass tubing is used in various manufactured articles and considerable pipe is made of this alloy. Large amounts of high brass wire are used in the manufacture of screws and rivets and for various heading jobs of this type.

Corrosion of High Brass—Much of the difficulty encountered in the use of high brass has been with the phenomenon known as season cracking.²⁰ Intercrystalline cracking in service, which is the same general action, occurs in several ways. It is caused by a combination of corrosion and stress, and the time element required to bring about failure is dependent on the severity of the corrosive action and the extent of the stress. Because of this, high brass, which is to be exposed to atmospheric conditions, is usually finished with a final annealing operation to relieve the internal stresses.²¹ If the corrosive action and stress are sufficiently severe the external stresses acting upon a structural member, in which the internal stresses have been relieved, are also likely to cause this type of failure.²²

It is, therefore, inadvisable to use high brass where it is subjected to severe external stress and exposure to the atmosphere. Ammonia compounds and mercuric salts are particularly active agents in causing this type of failure, and high brass should not be used where these chemicals are present.

Another difficulty encountered in the use of high brass caused by corrosion is known as dezincification. This phenomenon is usually encountered when the metal is used in contact with acids or with impure and salt bearing water. The action of a pure soft water is not injurious, but salt water and sometimes hard water are very likely to cause dezincification. The corrosion apparently proceeds by an electrolytic action which dissolves the surface at the point of contact and from the solution formed redeposits copper in a porous mass.²³ Occasionally this action will occur locally and penetrate a water tube or pipe in a very short time. In most cases, however, where soft water is to be carried, high brass can be used without danger from dezincification.

Specifications and Tests—The A.S.T.M. has developed standards for the specification and testing of sheet high brass. These standards have been changed from time to time, the most recent change being that made in 1938. These specifications (B36-38T) adopted the tensile test as the standard test for physical properties of hard rolled high brass. There are commercial objections to the use of the tensile test for control testing because of the time and expense involved in making the test. For specification work, however, no other test has been devised as yet, of as general application as the tensile test.

Above gages of about 0.020 in., the Rockwell test is generally satisfactory on hard rolled sheet. Below this gage the tensile test is the only test possible for

specification work. In the past the scleroscope test has been used for thinner gage material and is still used for control work on rolled sheets. It is subject to gage effects, however, and care must be taken in its use to make the results comparable. It is, therefore, not satisfactory for use in a general specification. Formerly the Brinell test was used in connection with the A.S.T.M. specifications but this test likewise is limited in its accuracy and usefulness to gages above 0.080 in.

Table II shows the present A.S.T.M. standards for the physical properties of rolled high brass. The specification takes care to point out that the Rockwell test values are to be used for general and approximate information only. The wide spread in Rockwell values listed are necessary, particularly in the less severely rolled material because of the effect of variations in the annealed condition before rolling. As the amount of rolling increases this effect has a lesser bearing on the ultimate Rockwell value.

In the case of annealed material, the grain size determination in acceptance standards has been adopted for the first time. Experience has increasingly shown that the grain size is the best measure of the usefulness of annealed high brass for any particular purpose because it is applicable uniformly throughout the entire range of commercial thicknesses. As an aid in controlling and checking grain size values, some data are included on the Rockwell hardness of annealed sheets. As in the case of hard rolled sheets, these values are for informatory purposes only and of the two cases the Rockwell values are more useful in the hard rolled tempers than in the annealed material. Table II shows the specified properties for annealed sheet.

*B and F Rockwell Hardness applies to metal 0.020 in. thick and over and 30T to hard metal 0.015 in. thick and over and annealed 0.012 in. and over.

How to Use High Brass—The question of exactly how to order high brass for any particular fabricated article is somewhat complicated. When there is a doubt as to just what to order, it is wise to take the problem up with the manufacturer and obtain the benefit of his experience.

(Continued on Next Page)

In general, articles requiring appreciable amounts of forming must be made from annealed (soft) brass. The question of the exact temper to be used is based on the amount of cold forming, the gage of the metal, and the surface required after forming. Many articles are required to withstand considerable forming without further annealing and must be in such condition after forming that they may

be readily polished. The grain size in such cases must be kept as fine as possible consistent with the forming operations, and these operations must be closely controlled so as not to stretch the metal unduly and open up the grains.

The balance between the temper of the material and the operation is a very delicate one, particularly in those cases where the forming operation will not allow ironing or smoothing the metal surface in the die. When the metal is to be given a number of draws and anneals, such as in pro-

Fig. 3—Comparative hardness data on sheet high brass.

ducing a drawn shell, the grain may be somewhat coarser. Even in these cases, however, the grain must not be so coarse as to produce a rough bottom on the cupped sheet, particularly if this is to be a part of the finished article. In some cases the surface appearance is of no importance and much deeper and more severe cupping operations may be performed on the sheet if it is produced with a coarse grain.

In the case of hard metal the Rockwell test is generally used for control purposes, and here again the decision of the proper temper to be used should be based on a full knowledge of the problem. When slight forming or bending operations are to be made, the material must not be too hard. While half hard temper is usually used for this, there are some instances

Fig. 4—Comparative test data used in controlling annealed high brass.

where even lighter tempers are required and metal less than one number hard must be furnished. When used for spring purposes or plate work, the metal must be rolled harder, depending on the surface required and, in the case of the springs or clips, the amount of bending required. It is helpful to lay out the blanking tools so that the bends will not be made parallel to the direction of rolling as the metal is much more liable to fracture if bent in this way. If it is necessary to bend the metal parallel with the grain, a less hard material must be furnished.

Fig. 5—Approximate bending characteristics of brass sheet.

The amount of bending which cold rolled brass will withstand depends primarily on the amount of cold rolling and, to a less degree, on the radius, and thickness of sheet. For comparative test purposes, the metal is usually bent on a radius equal to one-half the thickness of the sheet, and only sheet which has received reductions lighter than two numbers or half hard may be bent back on itself in all directions. If maximum hardness in the article is required, it is, generally, desirable to use as large a radius as possible and to make the desired bend across the direction of rolling. Fig. 5 shows some bending characteristics of sheet brass.

Properties of 80-20 Brass

By E. S. Bunn*

General—The alloy 80% Copper and 20% Zinc, commonly called "low brass", is a single phase, golden yellow alloy. It closely resembles, in most of its properties, the more ordinarily used 85-15 or red brass.

Desired mechanical properties are obtained by combinations of cold working and annealing. Hot working operations on 80-20 brass are successful only with careful control. In this connection, lead should be kept to a trace.

Physical Properties

Melting range	960-1000°C. (1760-1832°F.)
Density	8.67 gm/cm ³
Coefficient of thermal expansion (0-100°C.)	18×10^{-6} per °C.
Thermal conductivity	0.34 cal/cm ² /cm/sec/°C.
Electrical resistivity	5.3 microns/cm ²
Electrical conductivity	32.5% I.A.C.S. at 20°C.
Modulus of elasticity, psi.	1.5×10^7
Endurance limit, psi. (rotating beam machine. Determined on basis of 100 million cycles)	20,000-25,000

The 20,000 psi. endurance limit refers to soft 80-20 brass secured by annealing at 1100°F. for 30 min. The 25,000 psi. refers to hard 80-20 brass secured by rolling to No. 4 B. & S. gage.

Fig. 1—Variations in properties of annealed sheet of 80-20 brass by cold rolling to 0.042 in. thick.

Fig. 1 shows the changes in mechanical properties obtained on sheet annealed to an average grain of 0.020 mm. diameter by cold rolling over a range of 11-67% reduction in area (1-10 B. & S. gage numbers).

Whereas Fig. 1 illustrates the effects on mechanical properties of cold working of annealed material, Fig. 2 traces the effects of annealing following cold working. Annealed sheet, in Fig. 1, was cold rolled four B. & S. gage numbers (35.7% reduction in area) to a final thickness of 0.042 in., and annealed for one hour at temperature, over a range of 400-1300°F. at 100°F. intervals.

Fig. 3 shows the effect of the same annealing schedule as in Fig. 2 on tubing, extruded and cold drawn to $\frac{1}{8}$ in. outside dia. by .040 in. wall thickness. The physical properties for any annealing temperature vary from those in Fig. 2, principally because of differences in degree of cold working prior to annealing. Grain size prior to cold working is also a factor.

Mechanical Properties at Elevated Temperatures—W. B. Price¹ gives results of short time tensile at elevated temperatures on 30% cold drawn 80-20 brass. The tensile strength decreases almost linearly from a room temperature value of about 80,000 psi. to less than 10,000 psi. at 900°F. Elongation is at a minimum of zero at 480°F. as compared with a room temperature value of 13%. Beyond 480°F., the elongation steadily increases to the limit of the testing temperatures (1650°F.). At 1650°F. the elongation is 27%.

D. Bunting² shows by means of Izod impact tests the existence of a brittle range in annealed 80-20 brass between 800 and 1150°F. The testing range was from room temperature to 1300°F.

Uses—Some applications for 80-20 brass are: Forming operations not requiring the superior mechanical properties of an alloy in the 70-30 range of analysis; ornamental and architectural work, and hardware; applications involving some

*Asst. Director of Research, Revere Copper and Brass, Inc., Rome, N. Y.

corrosive conditions, as water pipe, and condenser tubing operating under certain corrosive conditions. As regards corrosion resistance, 80-20 brass is probably slightly less resistant to season cracking and dezincification than 85-15.

Fig. 2—Effects of annealing following cold working of 80-20 brass sheet cold rolled from four B. & S. gage No. to 0.042 in. thick then; annealed one hour at temperatures shown.

Fig. 3—Effects of annealing following cold working of 80-20 brass tubing. Extruded and cold drawn to $\frac{1}{16}$ in. outside dia. by 0.040 in. wall thickness, then annealed one hour at temperatures shown.

Properties of Wrought Copper-Aluminum Alloys

(Aluminum Bronze)

By Jerome Strauss* and Lewis H. Fawcett†

General—The practically important wrought aluminum bronzes, or aluminum-copper alloys rich in copper, generally contain from 4-10.5% aluminum with or without other metals. When the aluminum content exceeds 11% the alloy has a marked tendency to become brittle especially when appreciable amounts of other alloying metals are present. Iron is the additional element most usually employed. Nickel and manganese with or without iron are likewise used. The compositions in frequent use for wrought aluminum bronze are more numerous than in the case of cast aluminum bronze.

These alloys combine the strength and ductility of medium carbon steel with a high resistance to corrosion when subjected to the atmosphere, salt water, sulphuric acid, and other chemicals. They may be readily forged, hot rolled, or cold rolled and some of them are susceptible to heat treatment. Aluminum bronzes possess greater resistance to corrosion than manganese bronze, they have good bearing qualities, hardness, and resistance to shock and fatigue. These properties have caused wrought aluminum bronzes to be used for diaphragms and gears and in such applications as, rods and bars requiring great strength and resistance to corrosion, valve stems, propeller blade bolts, air pumps, condenser bolts, and for purposes requiring great strength combined with good bearing qualities, such as slide liners. Sheets and strips have been made into a large variety of products by cupping, spinning most frequent use in this country (others are listed in Table I):

Composition and Manufacture—The following compositions are the alloys in most frequent use in this country (others are listed in Table I):

Type	Copper	Aluminum	Per Cent			Specification	S.A.E. Grade No.	Use
			Iron, Max.	Other Additions Including Ni, Sn and Mn, Max.	Impurities Including Zn, Cd, and Pb, Max.			
88-9-3	84-93	7-10	4.00	2.00	0.25	{Federal QQ-B-666 {Navy 46B17	B ...	Rods, bars, shapes, forgings, and general use.
95-5	92-96	4-7	0.50	0.50	{Federal QQ-B-666 {Navy 46B17	A 701	Plates, sheets, and strips

Type 88-9-3 is used generally for all products excepting plates, sheets, and strips, in which case Type 95-5 is employed. Melting may be accomplished by any of the usual furnaces used in making high grade copper-base alloys using good melting practice. These alloys have high liquid shrinkage and it is good practice in teeming to use large end up ingot molds with hot tops similar to the practice used in manufacturing high grade alloy steels. Aluminum bronze has a great tendency to form dross and a large amount of this dross is found on the exterior of ingots made of this alloy. The dross may be removed by machining the entire surface of the ingot excepting the hot top and bottom. An optimum forging temperature range is 1700-1450°F. and reduction in forging should not be too rapid.

Types 88-9-3 and 95-5 do not require heat treatment. Aluminum bronzes are generally not heat treated unless their aluminum content is as high as 10%. The heat treatment generally consists of quenching in water from 1500-1600°F. depending on the cross section, followed by tempering between 700 and 1100°F. in accordance with the composition and section of each individual part. Cooling in air from the quenching temperature without tempering likewise is frequently done.

Aluminum bronzes are difficult to machine but with the use of high speed steel tools with lower rake angles than for steel they are machined in regular production without serious difficulty.

88.11	8.91	2.98	1 1/2 in. hot rolled, 1/2 in. sq. forged, 1550°F. (30) air	44,800	89,600	39.00	43.60
82.90	7.15	8.12	1/2 in. sq. forged, 1550°F. (30) air	49,650	48,400	52,350	60,100	94,450	28.00	39.30	31.8	207.9
82.90	7.15	8.12	1/2 in. sq. forged, 1550°F. (30) air	49,650	48,400	52,350	60,100	94,450	28.00	39.30	31.8	207.9

Mechanical Properties—Specimens should be of the usual form: 0.375 in. radius, 0.505 in. dia. by 2 in. gage length. The mechanical properties are as follows:

Mechanical Properties

	As Forged or Rolled	
	88-9-3	95-5
Tensile strength, psi.....	70,000-85,000	50,000-65,000
Proportional limit, psi.....	20,000-35,000
Yield point, psi.....	30,000-45,000
Elongation, % in 2 in.....	20-40	15-40
Reduction of area, %	20-40	15-40
Bend test	120°-180°	120°-180°
Resistance to impact (Izod), ft-lb.....	30-35
Brinell hardness number (500 kg. load).....	120-135	60-120

Especially high strength or high ductility not exhibited by the standard alloys outlined above may be secured with other aluminum bronzes, if desired for special purposes, by a judicious use of the proper proportion of aluminum along with one or more of the added elements—iron, nickel, and manganese. As in steel the presence of aluminum and nickel together give opportunity for precipitation hardening; the use of these alloys has, however, been slight. The composition, treatment, and mechanical properties of some of these alloys are given in Table I.

Corrosion—The wrought aluminum bronzes like cast aluminum bronzes are suitable for types of service such as exposure to industrial atmospheres, sea air, sea water, and a large number of neutral and acid salts in low concentration at both room and slightly elevated temperatures. In heat treated parts (9.5-10.5% Al) maximum resistance to mineral acids and their salts appears to be developed by tempering (after water quenching) at 900-950°F.

Specifications—Specifications covering wrought aluminum bronze in general use are as follows:

Society of Automotive Engineers Specification, No. 701; Federal Specification, QQ-B-666; and U. S. Navy Department Specification, 46B17.

The Society of Automotive Engineers specification covers in one grade the same composition that the Federal specification classifies by the two grades A and B. The U. S. Army use Federal specification, QQ-B-666.

Properties of Beryllium-Copper

By H. C. Jennison* and H. F. Silliman†

Alloys of beryllium and copper have been on the market in the United States since 1931. The important characteristic is the combination of high strength and hardness, high fatigue resistance, and high wear resistance in alloys which have the corrosion resistance of copper.

Composition—Beryllium-copper alloys containing up to approximately 2.75% beryllium can be produced in the form of sheet, rod, wire, and tube. With beryllium between 1.0 and 2.75% the alloy responds to a precipitation hardening heat treatment. Most of the wrought beryllium-copper available at the present time has the composition: Beryllium 2-2.25%, nickel 0.50% max., iron 0.25% max., copper balance. In tubes, the proportion of beryllium is lowered to facilitate drawing operations. The nickel content is added by one producer to refine the grain and increase the ductility.

Physical Properties—Table I gives the physical properties of beryllium-copper alloy.

Table I
Physical Properties of Beryllium-Copper Alloy
(Beryllium 2.00-2.25%)

Melting range.....	{Solidus 864°C. Liquidus 955°C.
Crystal structure, alpha phase.....	Face centered cubic
Lattice constant, alpha phase	3.56 Å
Crystal structure, gamma phase.....	Body centered cubic
Lattice constant, gamma phase	2.70 Å
Specific gravity.....	8.23 ± .02
Density	0.297 ± 0.01 lb./cu. in.
Maximum increase in density on heat treatment..	0.6%
Maximum decrease in length on heat treatment...	0.2%
Specific heat (30-100°C.).....	0.10 cal./g./°C.
Thermal conductivity (soft annealed).....	{0.16 B.t.u./sq. ft./in./sec./°F. at 68°F. 0.20 cal./cm. ² /cm./sec./°C. at 20°C.
Thermal conductivity (soft annealed, then heat treated)...	{0.20 B.t.u./sq. ft./in./sec./°F. at 68°F. 0.25 cal./cm. ² /cm./sec./°C. at 20°C.
Thermal conductivity (hard drawn).....	{0.14 B.t.u./sq. ft./in./sec./°F. at 68°F. 0.18 cal./cm. ² /cm./sec./°C. at 20°C.
Thermal conductivity (hard drawn, then heat treated)...	{0.16 B.t.u./sq. ft./in./sec./°F. at 68°F. 0.20 cal./cm. ² /cm./sec./°C. at 20°C.
Thermal coefficient of expansion (-50 to +50°C.).....	17 × 10 ⁻⁶ /°C.
Electrical resistivity at 20°C. (soft or hard drawn).....	60 ± ohms per mil ft.
Electrical resistivity at 20°C. (heat treated).....	41-59 ohms per mil ft.
Electrical conductivity at 20°C. (soft or hard drawn).....	17% ± I.A.C.S.
Electrical conductivity at 20°C. (heat treated).....	18-25% I.A.C.S.
Electrolytic potential	Negative to Hydrogen and slightly positive to Copper

Workability—Beryllium-copper may be cold worked by any of the processes which are applied to phosphor bronze in similar forms. It work hardens more rapidly than most wrought copper alloys so that annealing is required more frequently. Hot working by forging, extruding, and the like is possible but not so easy as with silicon-copper alloys, or aluminum bronze. Beryllium-copper can be soft soldered, silver soldered, and welded with the carbon arc. It can be plated with other metals by the usual methods. The alloy hardened by cold work, heat treatment, or both, is softened by heating to 775-800°C. (1427-1472°F.) and quenching rapidly in cold water. It may be hardened again by cold working and by reheating at a temperature in the range 250-325°C. (482-617°F.).

Beryllium-copper sheet, rod, wire and tubes, formed into various articles by cold working, do not require a solution heat treatment before hardening. Articles which have been formed by hot working, or articles which have been welded or hard soldered must be heated for 2 to 3 hours at 775-800°C. (1427-1472°F.) and quenched in water before they will respond satisfactorily to the precipitation hardening treatment.

The temper selected for any given article is governed by the amount of forming necessary. Sheet 0.050 in. and thinner in the soft, ¼ hard and ½ hard conditions can be bent back sharply upon itself when the bend is at 90° to the direction of rolling. For a similar bend parallel to the direction of rolling, only soft or ¼ hard strip should be used. For operations which draw the sheet, as in forming corrugated

*Deceased. †Metallurgist, American Brass Co., Waterbury, Conn.

diaphragms, the soft or $\frac{1}{4}$ hard temper is satisfactory. Any of the tempers mentioned above may be machined with ordinary cutting tools. In general it is best to select the hardest temper which will not fail in forming.

Tensile and Hardness Properties—Beryllium-copper may be heat treated to develop values of tensile and hardness exceeding those of the hardest wrought bronzes. The hardening is accomplished by heating the alloy for a definite period

Fig. 1—Strength of Precipitation Hardened Beryllium-Copper Alloy.

of time at a carefully controlled temperature in a muffle furnace, salt bath, or oil bath. Fig. 1 shows the time and temperature relationships for commercial heat treatments. In Table II are given some average tensile properties, and Table III shows the corresponding hardness values.

Fatigue Resistance—The 2.00-2.25% beryllium-copper alloy has a higher fatigue resistance than any other wrought copper-base alloy. Endurance limits of 45,000 psi. have been reported. Lower values are obtained occasionally, so it is considered safer to base designs on an endurance

limit of 35,000 psi. In comparable tests no reduction of the fatigue resistance was noted when the specimens were kept moistened with water.

Wear Resistance—Beryllium-copper has a better wear resistance than phosphor bronze when run against all grades of steel, especially under light loading and with no lubrication. It does not compare favorably in this respect with nitrided steels.

Applications—Beryllium-copper is used in the electrical and aircraft industries, and in other fields for parts such as springs, gears, diaphragms, bearings, and other articles where the electrical conductivity, corrosion resistance, nonmagnetic properties, machinability, and ductility are required.

Copper-Nickel Alloys

By E. M. Wise*

Copper and nickel form a continuous series of solid solutions free from phase changes. The melting temperature rises steadily with the nickel content. (The diagram¹ is shown on page 1353. The mechanical properties reach a maximum at about 65% nickel while the electrical resistivity attains a maximum at 55% nickel, as shown in Fig. 1. Both nickel and copper possess relatively high temperature coefficients of electrical resistivity but the temperature coefficient drops rapidly toward the middle of the series and is substantially zero in the 45% nickel-copper alloy known as Constantan.^{2, 3} The thermal emf. against copper also reaches a high value near the middle of the series, the maximum occurring at about 45% nickel.^{3, 10}

Nickel is magnetic at room temperature but loses its magnetism at about 360°C. The addition of copper to nickel depresses the temperature at which the magnetic change occurs, the 67% nickel 33% copper alloy becoming nonmagnetic at about 0°C.^{3, 4}

The addition of nickel to copper rapidly effaces the red color of copper, the 15% alloy having a faint pink cast while alloys containing 20% or more nickel are essentially white.

Copper-nickel alloys containing about 2% nickel have been found useful for mechanical purposes and are employed in England for fire boxes and the like, while the ductile 15 and 20% nickel-copper alloys have been employed for bullet jackets in small arms. A far more important application of the 20% nickel alloy was found in its use for condenser tubes, which was developed independently in this country and England. This was followed by the use of the superior 30% nickel-copper alloys which have proved outstanding in condensers for marine use and for salt water piping aboard ship. Large amounts of the latter alloy are also used for condensers in oil refineries. It is notably free from pitting tendencies and due to the fact that it does not support marine growths is "nonfouling". See Reference 5 for current observations on this and other condenser tube materials and the article on page 1415 dealing with this alloy.

The 25% nickel-copper alloy is familiar to all as it is the material used for the United States "nickel" coin.

The alloy containing 45% nickel, best known as Constantan, has a temperature coefficient of electrical resistivity which is practically zero, coupled with an electrical resistivity close to the maximum of the series. These characteristics make it broadly useful for a wide variety of electrical resistors in both wrought and cast form. The high thermoelectric force of Constantan against copper, iron and chromium-nickel and the reproducibility of the alloy make it popular for thermocouples for use at low and intermediate temperatures where high sensitivity is required. A number of other copper-nickel alloys containing from ½-65% nickel are employed for electrical purposes. The ½% alloy is used in conjunction with copper for extension leads for platinum rhodium-platinum thermocouples, while alloys containing 2½-22% nickel are employed for resistors where a moderate resistivity and an intermediate temperature coefficient are desired. The 65% alloy is used where a high resistivity and a fairly low temperature coefficient of resistivity coupled with higher resistance to oxidation are required.

The addition of a small amount of nickel to copper appears to have little effect on the rate of oxidation at temperatures ranging from 800-1000°C., but as the nickel content is increased beyond 30% a marked improvement occurs and the oxidation

Fig. 1—Mechanical and electrical properties of annealed copper-nickel alloys.^{3, 8}

*Assistant Manager, Research Laboratory, The International Nickel Co., Inc., Bayonne, N. J.

rate below 1000°C. falls rapidly to 70% nickel and then more slowly as pure nickel is approached. Reference 7 should be consulted for more detailed discussion. The effect of temperature upon the mechanical properties of copper-nickel alloys is considered in Reference 8.

The resistance of copper, nickel and copper-nickel alloys to a wide variety of corrosives is summarized in Reference 9.

The 65% nickel alloy known as Monel possesses the highest mechanical properties of the series, good fabricating characteristics plus excellent resistance to a wide range of corrosives. For these reasons, this alloy finds broad use in the process industries and for structures where mechanical strength and resistance to corrosion are required. It also finds use where good mechanical properties, plus high impact strength are required at very low (liquid air) temperatures, as well as in steam at 800°F. For full discussion, see page 1655 devoted to this alloy.

Regular wrought Monel is generally magnetic at room temperature but becomes nonmagnetic when warmed slightly. A similar behavior is shown by the 30% nickel-iron alloys and is employed in compensating for temperature errors in magnetic speedometers and electrical measuring instruments. By adding small quantities of silicon or aluminum to Monel the temperature of the magnetic change is depressed; as a result, cast Monel, which contains appreciable silicon, may be nonmagnetic at room temperature, and "K" Monel, which contains aluminum, remains nonmagnetic at sub-atmospheric temperatures.

Alloys containing nickel contents intermediate between Monel and nickel find little use although in England application has been made of the 90% nickel 10% copper alloy to the plates of radio diodes.

Effect of Impurities—Sulphur should be kept low in all of the alloys and should be under 0.02% and preferably under 0.01%. Carbon must be held to low levels in the wrought copper-rich alloys due to its tendency to precipitate as graphite under certain annealing conditions and this precipitate considerably reduces the normal high ductility of the alloy. In the wrought 20% nickel alloy carbon in excess of 0.04% or 0.05% may cause trouble, although with ½-1% manganese it is helpful in reducing this tendency to precipitate graphite. Larger amounts of carbon are permissible in castings and in alloys of higher nickel content, a carbon content of 0.20% being quite useful in cast 65% nickel (Monel).

Manganese is useful to control the effect of sulphur in low nickel alloys, but 0.1% of magnesium, actually introduced into the melt, is required with the nickel-rich alloys. About 1% of zinc, where permissible, is helpful in deoxidizing low nickel castings which are to be rolled. 0.5% silicon plus 1% manganese is effective in sand cast 30% nickel-copper while about 1.25% silicon and about 1% manganese plus a final addition of 0.1% magnesium is suitable for sand cast 65% nickel-copper alloy. For further details the sections of the Handbook dealing with specific alloys should be consulted.

Lead in the presence of the usual amounts of silicon is highly detrimental and is apt to cause cracking and very coarse structures in sand cast material and is detrimental to the high temperature properties, hence care should be taken to completely exclude lead from these alloys.

Annealing—For annealing, nonoxidizing sulphur-free atmospheres are desirable. The annealing temperature will vary with the alloy. Temperatures of 1200°F. are employed for the 20-25% nickel alloys and up to about 1600°F. for the high nickel alloys. More information for annealing specific alloys is given in other sections of the Handbook dealing with nickel-copper alloys.

Properties of Copper-Nickel Alloys

(Cupro-Nickel)

By H. C. Jennison* and W. S. Girvin†

The term "cupro-nickel" is a generic term applying to alloys composed entirely of copper and nickel (Cu and Ni are soluble in each other in all proportions). The principal cupro-nickel alloys at present contain nickel in the following percentages: 2½, 5, 10, 15, 20, 25, and 30.

Fig. 1—Annealing 15% cupro-nickel. Rolled to 0.04 in. thick and 5 B & S No. hard. Annealed ½ hr. at temperatures noted and quenched in water. Fig. 2—Annealing 20% cupro-nickel—same conditions as for Fig. 1. Fig. 3—Annealing 30% cupro-nickel.

The alloys with 15, 20, and 30% nickel are the most common. They have the following characteristics:

Nickel, %	Melting Point ¹ , °C.	Density, lb. per cu.in.	Electrical Conductivity, % I.A.C.S. at 20°C.	Temp. Coefficient of Electrical Resistance at 20°C.	Thermal ² Conductivity cal./sq.cm./cm./sec./°C. at 20°C.	Thermal ² Conductivity K. at 200°C.	Temp. Coefficient of Thermal Conductivity at 20°C.
15	1175	0.323	8.78	0.000344	0.112	0.144	0.00161
20	1200	0.323	6.474	0.000237	0.087	0.112	0.00163
30	1225	0.323	4.75	0.000048	0.069	0.088	0.00156

*Deceased. †Asst. Metallurgist, The American Brass Co., Waterbury, Conn.
 This article was not revised for this edition.

The 30% cupro-nickel is extensively used for condenser tube purposes and for handling salt water aboard ships and containers for handling corrosive substances in many branches of the chemical industry; also used for resistance wire. It can

Fig. 4—Rolling 30% cupro-nickel.

be hot forged, cold rolled or drawn and withstands severe bending operations. It is readily soft soldered, silver soldered, brazed, arc and gas welded. The melting point of 30% cupro-nickel welding rod is 1225°C. (2237°F.).

The 20% cupro-nickel is used for turbine blades and parts where resistance to corrosion and erosion is required.

Cupro-nickel being essentially a copper-base alloy has the fundamental corrosion-resistance associated with copper increased by the corrosion-resistance inherent to nickel. Cupro-nickel, like copper, is resistant to corrosion by all types of atmospheres, natural and industrial waters and sea water as well as many of the mineral and organic acids. Because of the high nickel content the alloys show superior resistance to alkalis. As the nickel content is increased to 30%, the corrosion resistance is improved.

Average Physical Properties of 20% Cupro-Nickel at Elevated Temperatures

Temp., °C.	Tensile Strength, psi.	Elongation in 2 in., %
22	64,560	15.5
70	60,820	15.5
120	60,010	12.5
170	56,730	11.5
220	55,790	12.0
270	52,810	11.0
320	50,910	10.5

Properties of the Alloy 55% Copper-45% Nickel (Constantan)

By G. C. Stauffer*

General—The 55% copper-45% nickel alloy has about the highest electrical resistivity, the lowest temperature coefficient of resistance, and the highest thermal emf. against platinum of any alloys of these metals. Because of these properties it is used in electrical resistors and thermocouples.

General Properties—The properties of this alloy are as follows:

Melting Point, °C.....	1210 (2210°F.)		
Density, g. per cm. ³	8.9 (0.322 lb./in. ³)		
	20-100°	20-500°	20-1000°C.
Linear Coefficient of Expansion, per °C.....	14.9 × 10 ⁻⁶	16.3 × 10 ⁻⁶	18.8 × 10 ⁻⁶
Thermal Conductivity, cal./cm./sec./C.*.....	0.0546		
Specific heat, cal./g.....	0.094		
Electrical Resistivity, microhm-cm.....	49		
	20-100°	20-250°	20-500°C.
Temperature Coefficient of Resistance ..	±00002	0	±000025
Thermal, emf. vs. platinum, 0°-1000°C. millivolts.....	43.92		
Tensile Strength, annealed, psi.....	60,000		
Tensile Strength, cold worked, psi.....	135,000		
Maximum temperature of use, for resistors, °C.....	500		
Maximum temperature of use, for thermocouples, °C...	900		

Thermal Emf.—The basic alloy is modified by additions of manganese and iron to give somewhat varied emf. as specified by pyrometer manufacturers. Representative values obtained by the United States Bureau of Standards are given in Table I. These values establish the shape of the temperature emf. curve.

Table I*
Emf. vs. Platinum Cold Junction at 32°F.

°F.	Millivolts	°F.	Millivolts
-300	+ 5.02	800	-17.41
-200	+ 3.73	900	-19.97
-100	+ 2.24	1000	-22.55
0	+ .57	1100	-25.15
100	- 1.27	1200	-27.77
200	- 3.26	1300	-30.39
300	- 5.39	1400	-32.99
400	- 7.64	1500	-35.58
500	- 9.98	1600	-38.14
600	-12.40	1700	-40.66
700	-14.88	1800	-43.13

*From Research Paper No. 1080, National Bureau of Standards, Washington, D. C.

Temperature Coefficient of Resistance—The change in resistance with temperature may be either positive or negative, depending on small variations in composition and on variations in the amount of cold working. In any case, the change is very small. Average values are given under General Properties for various temperature ranges.

*Driver-Harris Co., Harrison, N. J.

Properties of Cast Copper 45% Nickel Alloy*

By W. A. Graham*

The binary copper-nickel alloy containing 54-56% copper and 44-46% nickel is characterized by high electrical resistance and low temperature coefficient of resistance. The alloy is generally used in the wrought condition, but may be cast with satisfaction, yielding the following properties in the cast condition:

Ultimate tensile strength, psi. (Min. to average ¹).....	54,000-56,000
Yield strength, psi. (Average ²).....	21,000
Elongation, % in 2 in. (Average).....	32
Reduction of area, %.....	34
Brinell hardness, 10 mm. ball—500 kg. load.....	75-85
Rockwell hardness, $\frac{1}{16}$ ball—100 kg. load.....	B48-B54
Shearing strength, psi. (Approx.).....	43,000
Charpy impact resistance, ft.-lb. (Approx. ³).....	29.5
Specific gravity (Approx.).....	8.6
Weight per cu. in., lb. (Approx.).....	.309
Pattern maker's shrinkage, in. per ft.....	$\frac{1}{4}$
Solidification range, °C.....	1225-1275
Specific resistance, ohms per cir. mil. ft.....	294
Specific resistance, ohms per sq. mil. ft.....	231
Temperature coefficient of resistance, 0°-150°C. per °C.....	± 0.0001

¹Tension values determined from standard 0.505 test specimens cast in green sand molds.
²Yield strength defined as the stress at which the stress-strain curve shows a departure of 0.2% from the modulus line produced.
³Charpy impact values determined using 10 x 10 mm. specimens on standard Charpy machine.

General Properties and Uses—Pure copper and nickel are melted together usually in an arc furnace. The pouring temperature required is 1350°C., minimum. The melt is deoxidized just before pouring with a suitable deoxidizer such as magnesium. When pouring each mold, the gate should be kept full until the mold is filled. The rate of filling the mold should be controlled by the size of the runner and not by varying the rate of pouring.

Due to its electrical properties the alloy is primarily for use in grid resistors. It is customary to match high and low resistance grids so that the total variation per set is held to a minimum.

Effect of Various Elements on Tensile and Casting Properties—When small amounts of carbon, aluminum, and titanium are present, the general level of strength properties is raised, and in some cases the ductility is decreased. Silicon has a vigorous effect on the physical properties, and an increase in silicon in the above mixture to 0.75% results in a tensile strength of approximately 75,000-85,000 psi. and a yield point of 55,000-60,000 psi. and a Brinell hardness number of about 170. The ductility is reduced sharply with increased silicon and is of the order of 12-20% at the 0.75% silicon level. In general, it is preferable to keep silicon nearer 0.5% as the higher silicon alloys are somewhat sensitive to hot cracking. Iron, up to 1.50% increases the yield point and proportional limit quite sharply, and the tensile strength moderately, without loss of ductility but excessive amounts are undoubtedly detrimental from a corrosion standpoint. Manganese has a rather mild effect on the tensile strength but is decidedly helpful from a casting angle, as its presence with silicon improves the fluidity of the alloy. It also materially improves the resistance of the casting to hot cracking when subjected to stress while cooling in the mold.

Lead is extremely deleterious in the silicon containing cupro-nickel, giving rise to excessive hot cracking, rendering the alloy useless. It should be virtually excluded from the mixture.

Uses—The alloy is used for cast fittings such as couplings, tees, ells, pump and valve bodies, and employed in conjunction with the wrought 70:30 copper-nickel alloy, which finds use in marine salt water lines, condensers in marine and seaboard applications and in oil refineries.

Cupro nickel castings (30% nickel) of various types may also be used under service conditions where physical properties and corrosion resistance intermediate between those of nickel-silver and various high nickel content alloys are appropriate.

Foundry Practice—A method for the production of pressure tight castings in this alloy has been recently described by the author.¹

Properties of Copper-Silicon Alloys*

General—The cast and wrought copper-silicon alloys usually contain one or more other elements and are of commercial importance because they resist the action of many corroding agents and have the strength of mild steel. They can be cast, rolled, spun, stamped, forged, and pressed either hot or cold and can be readily welded by all the usual methods. They are supplied in the form of sheets, strip, plates, wire, rods, tubes, pipe, casting ingots, hot pressed parts and special shapes.

Composition and Physical Constants—The trade name, manufacturer, nominal composition, physical constants, and A.S.T.M. specification number and type are given in Table III.

Mechanical Properties—Mechanical properties of sheets, strip, plates, rods, bars, shapes and wire are given in Tables I, II, IV, and V, which are taken from various A.S.T.M. specifications listed in Table III.

Castings—With correct foundry practice, standard tension test specimens, poured from copper-silicon alloy ingots in sand molds, and tested without machining, gave the following properties: Tensile strength, 40,000-53,000 psi.; elongation in 2 in., 25-50%.

Corrosion Resistance—These alloys, like copper, are satisfactory in contact with a number of corrosive solutions and compounds. This corrosion resistance may be adversely affected by the presence of oxidizing agents.

The alloys are employed in engineering construction because of their high strength combined with the fundamental corrosion resistance of copper and may be used in practically all locations where copper is satisfactory, but where greater strength than copper is desired.

The metal has been found of value for resistance to atmospheric corrosion in both industrial and marine locations and resistant to corrosion by sea water as well as corrosive industrial and natural waters, to sulphuric and hydrochloric acid and many of their salts, to alkalis and many of the alkali salts. It shows good resistance to certain organic compounds including alcohol, phenol, cresol, sugar solutions, fatty acids, and organic salts.

These alloys are under the Boiler Code Rules and are acceptable at a 10,000 psi. working stress for all temperatures from room temperature up to 250°F. Above 250°F. and up to a maximum of 350°F., these alloys are allowed a maximum working stress of 5,000 psi. The question of doubt in regard to contact with steam and

^aNo minimum grain size requirement is specified but all annealed material shall be fully recrystallized. ^bElongation may be determined in either the 2 in. or 10 in. gage length but not in both in any instance. ^cOn wire ¼ in. in diameter, the percentage of elongation shall be taken in 2 in. ^dThe term "Spring Temper" does not necessarily indicate a reduction of 8 B&S gage numbers on these alloy wires as in the case of brass.

steam mixtures is covered by a warning which appears in a footnote to the table of allowable working stresses on nonferrous materials which reads as follows:

There is doubt concerning the suitability of this material when exposed to certain products and/or high temperatures, particularly steam above 212°F., and the user should satisfy himself that it is satisfactory for the service for which it is to be used.

Workability—The copper-silicon alloys listed in Table III can be hot worked at 1100-1475°F., except Type D containing lead to make them free-machining. All alloys except Olympic C and Everdur 1000 can be cold worked commercially. They can be readily drawn, rolled, spun and stamped. The Type B alloys can be easily cold forged.

Welding Properties—Copper-silicon alloy can be satisfactorily welded by the oxy-acetylene, metallic arc, and resistance methods. For details of welding see page 220.

Annealing—Copper-silicon alloys Types A, B and D will recrystallize after severe cold reduction at approximately 750°F. and at somewhat higher temperatures following more moderate reductions. The annealing range suggested is from 900°F. for light anneals to 1300°F. for full anneals, depending somewhat on the size or thickness and the degree of softness desired. The oxide formed during annealing is particularly tenacious and the usual brass mill pickle solution containing 10-20% sulphuric acid leaves copper-silicon alloys with a thin oxide coating of dark red color. This red oxide surface is highly satisfactory for many uses. Except

where a bright surface is wanted for its color or for welding, this pickled finish is suggested as being satisfactory and less expensive.

The pickled copper-silicon alloy can be brightened by dipping in a solution composed of 15% sulphuric acid and $\frac{1}{4}$ lb. per gallon of sodium bichromate. The temperature of the solution should be held at approximately 100°F. After the metal is taken from this solution it should be thoroughly rinsed in cold water and then dipped for a few seconds in a solution composed of 15% sulphuric acid and 2% hydrofluoric. It should then be removed and given a thorough rinsing in cold water to remove any white deposit still clinging to the metal. If it is necessary to prevent water stains, the metal can be dipped in hot water and then dried on a hot sawdust bench. The usual precautions should be taken with the sulphuric-hydrofluoric dip to prevent fumes from injuring the work.

Properties of Cast Copper-Aluminum Alloys

(Aluminum Bronze)

By Jerome Strauss* and Lewis H. Fawcett†

General—Aluminum bronzes comprise a group of copper-base alloys containing from a small amount up to 16% of aluminum (more generally 5-11% aluminum) with or without appreciable additions of other metals. These additions are principally iron, nickel, and manganese; tin and zinc are occasionally used. The compositions in general use for sand or chill castings are less numerous than those used in the case of wrought material.

This group of alloys has high strength combined with ductility, low coefficient of friction against steel and some other metals, hardness comparable to manganese bronze and resistance to corrosion, to shock, and to fatigue. On account of these properties aluminum bronze has been applied in gun mounts, gears of various types for heavy machinery and light automotive construction, feed nuts, bearings, propellers, pump parts, fans, and ornamental work.

Composition and Application—Typical compositions used in the United States are as follows:

Type	Copper, %	Aluminum, %	Iron, %	Tin, %, Max.	Total Other Elements, %, Max.	Specifications
88-9-3	87.0-89.0	7.0-9.0	2.5-4.0	0.50	1.0	A.S.T.M.-B59-36
89-10-1	89.5-90.5	9.5-10.5	1.0 max.	0.20	0.50	A.S.T.M.-B59-36
90-9-1	88.0-92.0	7.0-9.0	1.25 max.	0.50	1.0
90-10	88.0-91.0	9.5-10.5	0.20	0.50	1.0

Type 88-9-3 is used generally, 89-10-1 where high tensile strength after heat treatment is required, while 90-9-1 is frequently used on castings of small cross sectional area (under $\frac{1}{2}$ in.). As type 90-10 contains no iron its yield point is apt to be low especially when slowly cooled after casting; this restricts its use somewhat, but for certain types of wearing qualities where neither high hardness nor ductility is required, this alloy is sometimes preferred.

Manufacture—Aluminum bronzes are difficult to cast due to high liquid shrinkage and a tendency to form dross, but these characteristics may be overcome by simple design, dry sand molds, the use of chills and good general foundry practice; as part of the last item, it is especially important to avoid turbulent flow of the metal into the mold. These alloys are not materially affected by the usual contaminating metals in small amounts but if consistently high physical properties are desired the use of commercially pure metals in preparing the alloys is recommended. Nickel or manganese as a major constituent increases the ductility over that found in the binary combinations, but they contribute less to elastic strength and hardness than does iron.

Aluminum bronze may be melted in the usual types of brass and bronze melting furnaces. The optimum pouring temperature may be as low as 1950°F. for heavy castings or as high as 2150°F. for light castings or those chilled over a large portion of their surface.

The 89-10-1 composition may have its strength increased by heat treatment;

Fig. 1—Test coupon and cast bar.

*Vice-Pres., Vanadium Corp. of America, Bridgeville, Pa., and †Metallurgist, U. S. Naval Gun Factory, Washington, D. C.

that is, usually quenching in water from 1500-1600°F., depending on the thickness and actual aluminum content, followed by tempering between 700°F. and 1100°F. in accordance with the section of each individual part.

Mechanical Properties—Test coupon and separately cast bar of the types usually used for these high shrinkage alloys are shown in Fig. 1. The specimen machined from these cast blocks should be of the usual form: 0.375 in. radius, 0.505 in. dia. by 2 in. gage length. The mechanical properties are given below:

Mechanical Properties

88-9-3, As Cast

Tensile strength, psi.....	65,000-75,000
Proportional limit, psi.....	20,000-25,000

Modulus of elasticity, psi.....	12,000,000-15,000,000

*0.5% permanent set.

Corrosion—The uses of the cast aluminum bronzes have been briefly noted earlier in this article. It need merely be stated here, therefore, that the types of service for which these alloys are suited include also exposure to industrial atmospheres, sea air, sea water, and a large number of neutral and acid salts in low concentration at both room and slightly elevated temperatures.

Specifications—Specifications in general use covering aluminum bronze castings are as follows: A.S.T.M., B59-36; S.A.E. No. 68; Federal Specification, QQ-B-671, and U. S. Navy Department Specification, 46B18.

The S.A.E. specification conforms to the A.S.T.M. specification B59-36 and the Navy Department specification conforms in technical details to Grade A of the Federal specification. The U. S. Army uses Federal specification QQ-B-671.

Properties of Cast Copper-Lead-Tin Alloy

(Cu 80%, Pb 10%, Sn 10%)

By Dr. G. H. Clamer*

The alloy known as 80-10-10 is a copper base alloy composed of 80% copper, and 10% each of tin and lead, and may contain from traces up to 1% of phosphorus. When the phosphorus content approaches 1%, it is known as 80-10-10 phosphor bronze.

The alloy is primarily a bearing metal and was developed to replace the so-called copper-tin bronzes formerly used for such purposes. The addition of lead resulted in greatly improving the antifrictional qualities of the alloy. It also had the effect of facilitating machining, and improving casting properties. As a result this alloy has widespread acceptance as a standard bearing metal.

It is estimated that in excess of 10,000,000 lb. of this alloy are cast annually in the United States.

Structure—Microstructurally, this alloy consists of a matrix of copper and tin, containing a small amount of lead in solution, the balance of the lead being mechanically held. The constitutional diagram of the matrix is shown in Fig. 1, page 1365.

Composition—Although there are a number of specifications covering this alloy, the one most widely used is that of the A.S.T.M., B30-36, Alloy No. 16.

Specification B30-36

	Desired, %	Min., %	Max., %
Copper	80	79	..
Lead	10	9	11
Tin	10	9	11
Zinc	0.50
Phosphorus	0.05	..
Antimony	0.50
Nickel	0.25
Iron	0.25
Sulphur	0.08
Aluminum	None
Silicon	0.03
Other than copper, lead, tin, zinc, nickel, and antimony.....	0.50

Effects of Major Constituents—Increase of tin increases the hardness and compressive strength of the alloy and also increases the rate of wear. Increase of lead promotes plasticity of the alloy, gradually decreases strength, improves machinability, and lowers elongation. Phosphorus when added in small amounts acts as a deoxidizer and when present in appreciable quantities increases hardness, tensile strength, and fluidity of the alloy, and lowers its melting point.

Impurities—**Zinc**—Zinc within limits of specification has no detrimental effect on this alloy when phosphorus is present in amounts not exceeding 0.05%. However, when an appreciable amount of phosphorus is present, it increases grain size and lowers the physical properties of the alloy. It also has a tendency to increase the rate of wear and to cause lead segregation.

Antimony—Antimony increases the grain size and lowers the physical properties of the alloy.

Iron—Iron is an impurity in the alloy. It is found in solution or in the free state. In both cases it is detrimental and should be kept as low as possible. When in the free state it makes hard spots, and when in solution it increases internal shrinkage and discolors the alloy.

Nickel—Nickel is not an objectionable impurity but is sometimes added for its ability to hold the lead and to increase the density of the alloy, which naturally increases its other physical properties.

Sulphur—Sulphur is an impurity in this alloy. There is some question as to the amount necessary to produce distinctly harmful results. Recommended prac-

*Pres. and Gen. Mgr., The Ajax Metal Co., Philadelphia.

tice relative to this impurity awaits results from work now in progress. Up to 0.08% is not considered harmful.

Aluminum—Aluminum is an extremely dangerous impurity and even a few hundredths of a per cent is likely to ruin the alloy, making it unsound. Aluminum apparently alters the crystalline structure of the alloy markedly, even small amounts cause lead sweats.

Silicon—Silicon has somewhat the same effect as aluminum on this alloy. It causes excessive dross formations and general unsoundness, and imparts a white discoloration on the surface of the castings. It also has the effect of producing lead sweats.

Properties of Wrought Manganese Bronzes

By H. C. Jennison* and V. P. Weaver**

The wrought manganese bronzes covered by this article are copper-zinc alloys of the Muntz metal type improved by the addition of small amounts of manganese, tin, and iron. Tin imparts appreciable hardness and strength and also noticeably improves corrosion resistance by reducing dezincification, a type of attack to which such alloys are prone. Iron also increases the hardness and strength and acts as a grain growth inhibitor. Manganese also refines the grain structure, increases strength, and improves the working properties. The following composition limits are specified in Federal Specification QQ-B-721a (Class A) and United States Navy Department Specification 46B15c covering manganese bronze bars, plates, rods and shapes: copper, 57-60%; tin, 0.5-1.5; iron, 0.8-2.0; manganese (max.), 0.50; aluminum (max.), 0.25; lead (max.), 0.20; other impurities (max.), 0.10; and zinc, remainder.

A typical nominal composition is 59% copper, 39% zinc, 0.5% manganese, 0.8% iron, and 0.7% tin.

The approximate physical properties are as follows:

Melting point, °C.....	896
Electrical conductivity, % I.A.C.S. at 20°C.....	24.6
Thermal conductivity, cal. per sq. cm. per cm. per sec. per °C. at 20°C..	0.241
Average coefficient of linear expansion per °C. from 25-300°C.....	0.000021
Specific gravity.....	8.365
Density, lb. per cu. in.....	0.302
Modulus of elasticity, in tension, psi.....	15,000,000

The usual requirements for tensile properties in accordance with the aforementioned Federal Specification (Class A) are given in Table I:

Table I
Tensile Properties of Wrought Manganese Bronze

¹When round specimens, other than type 1 are used for testing rods, bars, and shapes, elongation shall be determined on a gage length of 4 times diameter. ²Soft rods and bars are intended for reforcing. ³No requirement.

Manganese bronze has relatively poor cold working properties but excellent hot working properties. Forging is best done in the temperature range from 650-750°C. The machinability is rated at about 30% that of free cutting yellow brass rod. The alloys are readily welded by the oxy-acetylene torch and with zinc-free copper alloy welding rods such as some of the phosphor bronzes and copper-silicon alloys, carbon arc welds of moderate strength can be obtained. Because of the high vaporization of zinc from the base metal, they are not suited to metallic arc welding but thin sheets can be resistance welded.

*Deceased. **Assistant metallurgist, The American Brass Co., Waterbury, Conn.

Manganese bronze is available in the form of bars and plates, rods, shapes, sheets, strips, wire and die pressed forgings. Material manufactured to the above mentioned specifications may be either hot or cold finished and is annealed or treated to meet the mercurous nitrate strain test. Such material is intended for purposes requiring great strength and incorrodibility such as valve stems, propeller blade bolts, air pumps, and condenser bolts and may be used in lieu of Naval brass where high strength is required.

Manganese bronze under some conditions is subject to season or corrosion cracking; it should, therefore, be manufactured to meet the strain test requirement of standard specifications and special consideration should be given to working stresses.

Manganese bronze welding rod is made to the following composition requirements of Federal Specification QQ-R-571 and Navy Specification 46R1b covering Nonferrous Welding Rods for Gas Welding: copper, 57.0-60.0%; manganese, 0.3-1.0%; iron, 0.3-1.0%; tin (max.), 1.0%; lead (max.), 0.15%; aluminum (max.), 0.15%; and zinc, remainder.

Such rods are used for general welding of brass and bronze sheets, plates, shapes and castings. Manganese bronze welding rod is also used for the oxy-acetylene welding of steel, cast iron and malleable cast iron and for building up wear resisting surfaces.

The wrought manganese bronzes belong to that group of alloys known as "high tensile strength brasses."

The Properties of Cast Manganese Bronzes

By Lewis H. Fawcett*

Introduction—Manganese bronze is a copper-zinc alloy containing aluminum, manganese and iron; and occasionally nickel or tin. It is also (and more correctly) referred to as manganese brass, aluminum brass, complex brass, high strength brass, high tenacity brass and high tensile brass. Apparently the first public mention of manganese bronze is to be found in "The Times" (London) of February 21, 1876. This article cited the results of mechanical tests made at the Royal Arsenal, Woolwich, on certain new alloys (copper-tin-iron-manganese bronzes) introduced by P. M. Parsons. About 1888 Parsons replaced the tin in his manganese bronze by larger percentages of zinc, thus converting the alloy from one that had at least some small claim to the name bronze into a true brass, nevertheless the name bronze has persisted.

Application—Properly made manganese bronzes produce strong, ductile, non-magnetic castings possessing resistance to the corrosive action of sea water, sea air, waste water, industrial atmospheres and other corroding agents. Nevertheless, there is a probability of season cracking when manganese bronze is stressed above its yield point in certain applications such as valves. It is used for various parts of marine engine pumps, hydraulic machinery, valves, propeller hubs, propeller blades, engine framing, gears, worm wheels and general industrial purposes requiring high strength engineering castings.

Composition—The ranges of composition generally employed in this country for manganese bronze and high tensile manganese bronze are given in Table I.

Table I
Composition of Manganese Bronze

Elements	Manganese Bronze	High Tensile Manganese Bronze
Copper	55.00-60.00	64.00-71.00
Zinc	38.00-42.00	19.00-22.00
Tin	1.50, max.	0.02, max.
Manganese	3.50, max.	3.50-4.50
Aluminum	1.50, max.	4.50-6.00
Iron	0.40-2.00	2.00-3.00
Lead	0.40, max.	0.02, max.

The usual type of manganese bronze, namely, the type with higher zinc content, is approximately a 60-40 brass to which has been added small percentages of aluminum, manganese and iron, for example 58% Cu, 39% Zn, 1% Al, 1% Mn, and 1% Fe.

Manganese bronze of extremely high tensile strength may be made of a composition which is approximately: 67.50% Cu, 21% Zn, 5% Al, 4% Mn, and 2.5% Fe.

Physical and Mechanical Properties—The mechanical properties of a high-shrinkage alloy such as manganese bronze, are usually determined on a specimen cut from the test coupon of a separately cast bar such as shown in Fig. 1 in the article "Cast Aluminum Bronze." The machined specimen should be of the usual form: 0.375 in. shoulder radius, 0.505 in. dia. by 2 in. gage length. Physical and mechanical properties are given in Table II.

Manufacture—When passing from the liquid to the solid state manganese bronze has greater shrinkage than most brass or bronze alloys. It also has a strong tendency to form dross and scum. These difficulties may be overcome by care in design, the use of dry sand molds, chills, massive feeder heads, the prevention of turbulent flow of metal into mold, and good general foundry practice. Manganese bronze may be melted in the usual types of furnaces used in melting brass, bronze and other nonferrous metals and alloys.

Specifications—Specifications covering manganese bronze castings are as follows: A.S.T.M., B54-27; S.A.E. No. 43; Federal Specification QQ-B-726; and U. S. Navy Department Specification 49B3.

*Metallurgist, U. S. Naval Gun Factory, Navy Yard, Washington, D. C.

Properties of Copper-Nickel-Tin Alloy†

By W. B. Price*

This alloy contains nominally 70% copper, 29% nickel, and 1% tin. The proportion of copper and tin is the same as in regular Admiralty condenser metal, while nickel replaces a like percentage of zinc.

Physical Properties and Composition—Typical tension test values obtained on 1 in. hot rolled hexagon rod are:

Composition, %			
Cu	69.12	Elastic limit, psi.	30,500
Fe	0.18	Yield point, psi.	35,800
Sn	1.03	Tensile strength, psi.	64,500
Ni	28.23	Elongation, in 2 in. %	46
Mn	0.94	Reduction in area, %	72.2
S	0.01		
C	0.06		
Zn	0.43 (difference)		

The alloy is readily hot rolled between 2000 and 1550°F. or may be cold rolled or cold drawn. When cold drawn to wire of 0.006 in. dia. with 99.6% final reduction, the alloy has a tensile strength of approximately 131,000 psi., and an elongation of 2% in 2 in. In the annealed state this wire has a tensile strength of approximately 77,000 psi., and an elongation of about 35% in 2 in.

Fig. 1—Annealing test on hot worked 0.102 in. strip. Analysis: Cu 71.21%, Fe 0.35%, Sn 1.07%, Ni 26.42%, C 0.04%, Mn 0.56%, Si 0.12%, Zn (diff.) 0.23%. Material cast and hot worked to 0.599 in., then cold rolled to 0.102 in., 15 No. hard (reduced 83%) before annealing.

Fig. 1 shows the recrystallization temperature of the alloy when very hard worked to be about 1040°F. Grain growth after recrystallization is nearly in direct proportion to the annealing temperature.

Fig. 2—Effect of cold rolling on tensile properties of strip. Anneal at 1435°F. before rolling. Gauge: Soft 0.102 in.; 10 No. hard 0.032 in. Composition same as Fig. 1.

*Chief Chemist and Metallurgist, Scovill Mfg. Co., Waterbury, Conn.

†The trade name of this alloy is Adnico.

Fig. 2 and 3 show the effect of cold rolling on the physical properties of strip.

Fig. 3—Effect of cold rolling on hardness of Admic strip. Anneal at 1435°F. before rolling. Gage: Soft 0.102 in.; 10 No. hard 0.032 in.

Fig. 4 shows the improvement that may be effected in cold drawn wire by slight alteration of chemical composition. This wire contained 3% less copper, 3% more nickel and ½% more zinc. The lower Cu, higher Ni material was originally softer, hardened faster and reached a greater final strength.

Fig. 4—Effect of cold drawing on tensile properties of wire. Analysis: Cu 68.15%, Fe 0.60%, Sn 1.11%, Ni 28.37%, C 0.04%, Mn 0.51%, Si 0.05%, Zn (diff.) 1.17%. Material cast and hot worked to ½ in. wire, then cold drawn. Gage: Soft 0.257 in. (grain size of 0.045 mm.); 10 No. hard 0.081 in.

In Fig. 5 the results of short time tension tests at elevated temperatures are given. The alloy used in these tests was annealed 1 in. rod, having a tensile

Table I
Creep Characteristics By "Up-Step" Loading

Temp., °F.	Stress for Designated Rate of Creep Rate = % per 1000 hr.		
....	0.01	0.10	1.00
600	13,800	18,900	25,500
800	4,500	7,900	14,000
1000	630	1,300	2,700

strength of 64,000 psi. The yield point and elastic limit values are abnormally high for an annealed nonferrous alloy, which is probably due to a carbon content of 0.11%, approximately twice the normal.

The results of creep tests¹ at 400, 600, 800, and 1000°F. are shown in Fig. 6 and Table I. The data were determined by the "up-step" loading method. This method consists of applying a fixed load and holding constant until creep either proceeds at

Fig. 5—Short time tensile properties of Cu, Ni, Sn alloy rod at elevated temperatures.

a constant rate for at least 200 hr. or until it comes to a complete stop for at least 200 hr. The load on the specimen is then increased and the procedure repeated.

Fig. 6—Time by elongation curves of Cu, Ni, Sn alloy at 400, 600, 800, and 1000°F.

¹A. E. White, O. L. Clark, and L. Thomassen, An Apparatus for the Determination of Creep at Elevated Temperatures, Trans., Am. Soc. Mech. Eng., Fuel and Steam Power Section, v. 52, No. 27, p. 347.

The load carrying ability at 800°F. is somewhat better than that of plain carbon steel at 1000°F., since the value usually reported for a rate of flow of 0.01% per 1000 hr. for carbon steel at 1000°F. is about 3,500 lb. It is doubtful if this copper alloy can be successfully used at 1000°F. except in cases where a large amount of deformation can be allowed.

At 400°F., the elastic plus plastic deformation occurs immediately upon the application of the load, or within a relatively short time afterwards, and then creep comes to a complete stop, at least within the sensitivity of the equipment used.

Corrosion Resistance—The corrosion resistance of this alloy is an important factor in many of its applications. It is basically a copper-nickel alloy of the type that has been used extensively because of its resistance to corrosion, but its properties are enhanced by the addition of tin. For general guidance the following typical application may be noted:

Condenser Tubing	Laundry Machining
Table Ware—Restaurant Ware	Pulp and Paper Machinery
Diaphragm Metal	Plumbing Supplies

Cast Copper-Nickel-Tin Alloys (Nickel Bronzes)

E. M. Wise*

The addition of from ¼-2% nickel to the commonly employed tin bronzes increases the strength properties, particularly the yield strength, and improves fluidity, reduces the grain size and aids in securing hydraulic tightness.^{1,2} A broad range of nickel bronzes can be further hardened and strengthened by conventional age hardening treatments analogous to those employed with duralumin and beryllium copper.^{3,4,5}

Reference to the copper-nickel-tin diagram⁶ on page 1371 will show that a considerable change in the solid solubility of a nickel content phase occurs with a

Fig. 1—Properties of nickel bronzes as cast and after heat treatment.

change in temperature and it is this characteristic which permits these alloys, over a considerable range of composition, to be softened by annealing at 1400°F. and cooling, and subsequently hardened by heating for a few hours at 550-600°F. While the highest properties are secured by the above treatment, substantial hardening can be achieved by merely aging the cast alloy for about 5 hr. at about 600°F.

The presence of lead in castings which are to be used as cast is no more detrimental to the properties than in nickel-free bronze, but lead must be excluded rigorously from castings which are to be heat treated as even traces seriously reduce the elongation and retard the age hardening reaction.

*Assistant Manager, Research Laboratory, The International Nickel Co., Inc., Bayonne, N. J.

The properties of as cast nickel bronzes and those of homogenized, quenched and aged alloys as reported by Wise and Eash¹ are shown in Fig. 1. As will be observed, the strength properties for a given copper content tend to reach their maxima when the nickel and tin contents are equal. The effect of temperature of aging upon the hardness and tensile properties of the 5% nickel 5% tin 2% zinc alloy is shown in Fig. 2.²

Fig. 2—Effect of aging upon the cast and heat treated 5% nickel 5% tin 2% zinc alloy.

Fig. 3—Relation between tensile strength, proportional limit, and elongation.

In common with other age hardened alloys, precipitation hardening occasions some reduction in ductility. The relation between proportional limit, tensile strength, and elongation for the cast and heat treated 5.0% nickel 5% tin alloy is shown in Fig. 3.³ Relations of this type permit a proper balance to be struck between the strength and elongation to meet particular engineering requirements.

It may be remarked that the 7.5% nickel 8% tin 2% zinc composition is rather vigorous in its response to age hardening and for general application the slightly softer 5% nickel 5% tin alloy generally provides sufficient strength and is readily handled in the foundry. It is also a good general purpose alloy for use in the as cast state without heat treatment. The melting and casting of this alloy have been studied in considerable detail by Kihlgren whose recent paper should be consulted for detailed information.⁴

The composition and properties of the sand cast 5% nickel 5% tin 2% zinc alloy are as follows: Nickel, 5-5½%; tin, 5-5½%; zinc, 1-2%; phosphorus, .03-.05%; lead, absent; iron and other impurities low, and the balance copper.

	Tensile Psi.	Yield Point, Psi. (0.5% under load)	Elongation, % in 2 in.	Brinell Hardness No., 1000 kg.
As cast	48,500	24,400	40	85
Cast and aged, 550°F. for 10 hr.	73,000	61,000	5	170
Cast and annealed, 1400°F. for 10 hr., quenched and aged, 550°F. 5 hr.	87,000	70,000	10	190
By adjusting the aging temperature, the properties can be had.....	70,000- 90,000	50,000- 70,000	25-5	140-200

Melting Practice and Heat Treatment—The melting and casting of nickel bronzes follows good bronze practice. Melting under oxidizing conditions is desirable and, in alloys to be age hardened, definite oxidation of the copper-nickel base is important. This is accomplished by melting the copper and nickel under a light charcoal cover and stirring in 0.2% of cuprous oxide when the charge has melted. The oxides

are then reduced by adding 0.03% phosphorus and the zinc and tin are introduced. A final addition of 0.05% phosphorus has been found effective with the 5% nickel 5% tin 2% zinc alloy. Other deoxidizers, such as 0.15% silicon plus 0.6% manganese or 0.05-0.1% barium have been found effective in the 7.5% nickel 8% tin 2% zinc alloy but if silicon is employed in the 5-5 alloy an increase in nickel content of about 1% must be made to secure age hardening.

As earlier mentioned, lead must be excluded from castings which are to be heat treated and for this reason good quality virgin metals and only clean revert scrap should be employed for such castings.

The annealing or homogenizing treatment is usually carried out at 1400°F., five hours at temperature being sufficient for most compositions. The rate of cooling from the homogenizing temperature can be varied within wide limits without much effect on the properties after aging, although water quenching or air cooling are usually most suitable. The time and temperature of aging are selected to give the most desirable combination of strength and elongation, 550-600°F. for 5 hr. being generally suitable for the 5% nickel 5% tin and 7.5% nickel 8% tin alloys of commercial purity. The rate of cooling from the aging temperature is unimportant.

Properties of Copper-Nickel-Zinc Alloys

By H. C. Jennison* and W. S. Girvin†

Composition—The alloy†† has a composition of copper 75%, nickel 20%, and zinc 5%. It has a bright nickel-like appearance. Another copper-nickel-zinc alloy known as alloy 854 contains 30% nickel instead of 20% and 5% zinc. These alloys can be bent, stamped, spun, formed, drawn cold, or hot forged. Being a copper-base alloy it has the fundamental corrosion resistance associated with copper but increased by the nickel additions.

These alloys resist corrosion in all types of atmospheres; natural and industrial waters and sea water, as well as many of the mineral and organic acids. They are of

Fig. 1—Sheet of alloy 850 rolled from 5 B & S No. to 0.032 in. annealed 1/4 hr. at temperature indicated.

Fig. 2—Sheet of alloy 850, 0.145 in. gage rolled to 0.045 in.

particular value where resistance to corrosion by impingement attack is encountered, such as in condenser tubes and piping for handling salt water and alkalis.

Annealing—The annealing temperature is 1100°F. For deep drawing, an annealing temperature of 1475°F. should be used.

Physical Properties

Density at 20°C. (68°F.):

8.84 g. per cc.
0.320 lb. per cu.in.
553 lb. per cu.ft.

The density is 0.62% less than copper. If accurate weights are required multiply the values in standard copper weight tables by 0.9938.

Electrical resistivity at 20°C. 172 ohms per circular mil-ft. Circular mil-ft.—172 ohms.

Melting point—1150°C. (2102°F.).

Coefficient of thermal expansion—0.0000164°C.
0.0000091°F.

Modulus of elasticity—19,000,000 psi.

Mechanical Properties (Room Temperature)—Minimum tensile properties of this alloy in its several forms are given below and in Fig. 1 and 2.

570	20,760	13.5

Applications—This copper-nickel-zinc alloy is being used for making screen cloth, tableware, window and door frames, tubes for oil coolers, heat exchangers, salt evaporators, and condenser tubes. The metal can be used as welding rod on a wide variety of base metals. It can be used with either the oxy-acetylene or electric methods. The alloys are available in the form of wire, rods, bars, sheets, strips, tubes, and shapes.

Castings—Casting ingots are produced in both the 20 and 30% alloys. The chemical and physical properties of the 20% alloy are as follows: Cu 64.5%, Zn 7.5%, Ni 20.0%, Pb 5.0%, and Sn 3.0%.

Properties of Wrought Nickel Silvers

(Copper-Nickel-Zinc Alloys)

By T. E. Kihlgren*

The nickel silvers are alloys of copper, nickel, and zinc which owe their importance to color, a degree of corrosion resistance higher than that of the common brasses, good mechanical properties, moderate cost, reasonably good productive facility, and availability in a wide variety of cast, rolled, and extruded shapes. In addition to white alloys, subdued pink, green, and yellow tints can be secured by suitable adjustment of copper, nickel, and zinc contents, and these colored alloys have useful architectural applications.

Fig. 1—Composition ranges of nickel silvers.

containing about 18% nickel, 17-20% zinc, balance copper. In some instances about 1% of lead is added to improve the machinability, particularly when the alloy is in rod form.

Where deep drawing properties are required, however, lead is undesirable, and this element is also frequently responsible for "fire cracking." The low zinc alloys may be satisfactorily worked both hot or cold. The best known of these is the 20% nickel alloy with 5% of zinc. At the 30% nickel level the 5% zinc alloy formerly produced has been largely supplanted by a simple 30% copper-nickel. A small amount of zinc is sometimes added to the latter to obtain sound sheet bars, only a trace usually remaining in the metal.

The extruding alloys are only hot worked, possessing poor cold workability, the presence of the body-centered beta phase conferring an excessively rapid rate of work hardening. The hot working properties are excellent and 8, 10, 13 and 15% nickel extruding alloys are readily produced, in a multitude of shapes, and are also hot forged.

The casting alloys are not included in this survey, but it may be remarked that these often contain, in addition to copper, nickel, and zinc, appreciable amounts of tin and lead, both of which improve the casting properties.

Mechanical Properties of Cold Workable Alloys—While the properties of the nickel silvers will be more completely discussed under individual headings in other articles dealing with specific alloys, a brief summary of the properties as a function of the nickel content is appropriate. Fig. 2 is based on the work of Cook¹ who presents comprehensive and sys-

Fig. 1 shows in a general way the composition ranges of the nickel silvers, although in any given field it should be realized that the commercially important alloys are confined to relatively small areas. The cold working alloys which possess the face-centered cubic structure designated as alpha contain from 7-30% nickel. In general, as the nickel content is increased the zinc content is lowered and a constant copper content of 60-65% gives alloys which are commercially practical.

One of the most widely used of the wrought nickel silvers is "18% nickel silver"

containing about 18% nickel, 17-20% zinc, balance copper. In some instances about 1% of lead is added to improve the machinability, particularly when the alloy is in rod form.

Fig. 2—Properties of nickel-silver of varying nickel content; copper 62% (Cook¹).

*Metallurgist, The International Nickel Co., Bayonne, N. J.

tematic data on the hardness and mechanical properties as affected by cold work, and the annealing characteristics, of seven nickel silver alloys of sensibly constant copper content (60-65%), with nickel ranging from 10-30%.

In the annealed condition the properties increase with the nickel content, but after 60% reduction by cold rolling, changes in the nickel content between 10-30% have little effect. After a 90% reduction by cold rolling Cook finds that the lowest hardness value is obtained at the highest nickel level, suggesting that the extent of work hardening varies inversely with the nickel content at least in this range. The same author presents annealing curves to show that the recrystallization temperature increases with the nickel content, and as in brass, decreases as the cold work performed before annealing is increased. Cook's data³ on thermal conductivity, electrical resistivity and thermal expansion follow:

Nickel, ± 1%	Copper	Zinc	Specific Resistance Microhms- cm ³ ^a	Coefficient of Thermal Expansion 0-400°C. × 10 ⁶ ^a	Thermal Conductivity cal./cm ² /cm/ °C./sec. ^b	Temperature Coefficient of Thermal Conductivity

***1 in. diameter cast rods machined to 1/2 in. diameter.

Effect of Composition on Color.⁴—Nickel is the most important element in developing whiteness. Zinc in the presence of sufficient nickel also exerts a definite though less vigorous decolorizing influence. The relationship between composition and color of nickel-silvers containing 15-30% of nickel and 0-40% of zinc is schematically depicted⁴ in Fig. 3. There is of course no sharp transition from one field to the next, the colors merging gradually. The shaded area indicates the region of approximately white alloys. Colors are relative and some alloys outside the area, when viewed alone, will be "white" to all intents and purposes. For example, a 20% nickel, 15% zinc alloy possesses a white color when viewed by itself and it is only by placing in juxtaposition with alloys nearer the shaded area that its faint yellow cast is visible. It will be noted that as the nickel content is increased, less and less zinc is required to obtain a white alloy and at 30% nickel, 5% of zinc produces an essentially white alloy. At 13% nickel, upwards of 40% of zinc is necessary to secure whiteness.

Fig. 3—Color trends of copper-nickel-zinc alloys

In some instances, the ability to produce subdued color tints by suitable adjustment of the copper, zinc and nickel contents of the alloy offers interesting possibilities in decorative metal work, and is of interest to the architect. By suitable juxtaposition subdued color contrasts can be obtained using extruded, cast, rolled, and drawn sections.

Uses.—Nickel silver is used as a base for electroplated silverware, and for rolled gold plate in the jewelry industry, for architectural applications and ornamental metal work; for certain types of food handling equipment, marine fittings, and numerous other applications where a combination of a white color and a useful degree of corrosion resistance are required. Nickel silver is used extensively in

strip form for spring elements, especially in electrical relays, where its mechanical properties and ease of spot welding contacts makes it particularly advantageous.

Properties of Wrought 18% Nickel Silver (Copper-Nickel-Zinc Alloy)

By R. A. Wilkins*

Composition and General—The wrought 18% nickel silver alloys are predominately white in color, with strength, hardness and general corrosion resistance superior to the usual brasses.

The data herein apply, unless otherwise stated, to an alloy of the nominal composition, 18% nickel, 18% zinc and 64% copper. Other common 18% nickel silver alloys contain 10% and 27% of zinc. With increasing amounts of zinc, the tensile strength and hardness increase.

Nominal Composition : 64% Copper, 18% Zinc, 18% Nickel
Ready to Finish Grain : ——— 0.015 mm. ——— 0.070 mm.

Fig. 1 and 2—Mechanical properties of sheet rolled from metal of two different grain sizes as shown.

Fig. 3 and 4—Mechanical properties of rolled and annealed sheet.

Fabrication is usually accomplished by cold rolling and annealing, hot work being possible only when the zinc content is around 40%, or less than about 10%.

When the combined copper and nickel content is in excess of about 63%, the alloys structurally are simple alpha solid solutions.

Nickel is the most important element in producing whiteness of color, with zinc in a secondary role. For ordinary commercial applications, where whiteness is desired, the 18-18-64 alloy is acceptable.

*Vice President, Revere Copper and Brass, Inc., Rome, N. Y.

Physical Properties of 18-18-64 Alloy

Melting point, °C.....	1110
Density, g./cm. ³	8.72
Linear coefficient of thermal expansion (0-100°C.), °C.....	14.5×10^{-4}
Thermal conductivity, cal./cm. ² /cm./sec./°C.....	0.080
Specific electrical resistance at 20°C., microhms/cm. ²	27.55
Electrical conductivity, %, I.A.C.S. at 20°C.....	5.91
Modulus of elasticity.....	19.5×10^4
Endurance limit at 10 ⁸ cycles,* psi.....	17,500-21,500

*For an alloy of nominal composition, 18% nickel, 26% zinc, and 56% copper. Smaller value, annealed; larger value, 37% and 69% cold work.

Fig. 1 and 2 show the mechanical properties of sheet samples rolled from stock of two different grain sizes after varying degrees of cold work.

Fig. 3 and 4 show the physical properties of annealed material. Specimens were rolled 6 B&S gage numbers prior to finish annealing from stock of two different ready-to-finish grain sizes as indicated.

Workability—The wrought 18% nickel-silvers as indicated by the mechanical properties of annealed material, possess excellent ductility and as a result can be readily drawn, stamped, cold forged, coined, spun and otherwise fabricated.

The 18% nickel-silvers can be readily hard and soft soldered and joined by any of the conventional methods.

These alloys, while not as easy to machine as special free-cutting brasses, machine as well as the copper-zinc alloys to which they are structurally equivalent. Where special cutting properties are required, special alloys containing small amounts of lead are available.

Applications—Large quantities of 18% nickel-silver are used for plated silverware. Hardware, architectural details, ornaments, springs, resistance wire, and chemical equipment.

Properties of Wrought Leaded Nickel Silver

By T. C. Merriman*

General—Where lead is alloyed with nickel silver (copper-base alloy with zinc and nickel) it is usually done to promote machinability. Ease of machining is obtained at the expense of ductility; and in hard to spring tempers at the expense of strength. Leaded nickel silvers have practically all the advantages of the lead-free alloys of this type so far as color, resistance to corrosion and durability are concerned.

Composition—The three principal grades are 10, 12 and 18% nickel. In rod "full leaded" means 1% lead, but in sheet 10% and 12% "full leaded" usually means 2% lead. The grade (10, 12 or 18%) indicates nickel content, the balance being copper and zinc in the ratio of about two to one in the 10% and 12% nickel grades and about three to one in the 18% grade. Typical compositions are as follows:

Grade	Form	Copper, %	Zinc, %	Nickel, %	Lead, %
10 %	Rod	60	29	10	1
10 %	Sheet	60	28	10	2
12 %	Rod	60	27	12	1
12 %	Sheet	60	26	12	2
18 %	Rod	62	19	18	1
18 %	Sheet	62	19	18	1

Physical and Mechanical Properties

Specific gravity.....	8.7-8.8
Weight per cu. in.....	0.32 lb. approx.
Color.....	Yellow white to silvery white
Electrical conductivity.....	5.7-7% I.A.C.S.
Tensile Strength.....	55,000-120,000 psi. (rod)
Tensile Strength.....	54,000-95,000 psi. (sheet)
Elongation in 2 in.....	0.5-55%
Rockwell hardness.....	B 35-90 (sheet)

Typical values showing the variation of tensile strength and elongation for the 10% and 18% grades of leaded nickel silver at different tempers are shown in Fig. 1 for cold drawn rod, and in Fig. 2 for cold rolled sheet.

Fig. 1—Tensile properties of cold drawn leaded nickel silver rod.

Fig. 2—Tensile properties of cold drawn leaded nickel silver sheets.

Working—Leaded nickel silvers are hot short, and must be cold worked all the way from the chill mold casting. In general less severe reductions must be employed than are feasible for nonleaded nickel silver, both per operation and per cumulative cold reduction between anneals. Although these alloys can be cold worked to what might be called spring temper, there is little object in working either rod or sheet

*Metallurgist, The Seymour Mfg. Co., Seymour, Conn.

more than 4 B. & S. gage numbers hard, since the slight gain in strength is more than nullified by a tendency to brittleness.

Annealing—Leaded nickel silvers are very sensitive to heat, and while the nickel content suggests high temperatures, the lead will not permit, so a compromise is necessary. It is essential to bring the alloys up to heat slowly, and also to cool slowly. The importance of this cannot be overemphasized as fire cracking frequently results from neglect of such precautions.

Uses—Leaded nickel silvers find their principal uses in builders' hardware such as screws, keys, valves, nuts, bolts, lock parts.

Properties of Copper-Tin-Zinc Alloys

(88-10-2 and 88-8-4)

By Lewis H. Fawcett*

General—The casting composition known as 88-10-2 consists of approximately 88% copper, 10% tin, and 2% zinc. It is an ancient alloy which is still popular and important. The alloy 88-8-4 is a modification of 88-10-2. Both compositions are also known commercially as Government bronze, composition G, gun metal, Admiralty gun metal, and zinc bronze.

The importance of gun metal is due to a combination of properties, such as strength, toughness, bearing qualities, uniform shrinkage and contraction, good casting characteristics, and resistance to sea water corrosion and other similar severe conditions. It has a fine grained, more or less equiaxed crystalline exterior surface, with pleasing full red color, which will take a high polish. This fine grained surface is an aid in the prevention of leakage (if too much of it is not removed by machining) when gun metal castings are subjected to hydrostatic pressure.

Extremely slow cooling of gun metal, because of high pouring temperature or a large cross section of metal, is apt to result in hard spots caused by the local presence of a very high percentage of tin, indicating that the delta constituent, instead of being evenly distributed, has formed in large masses, making the machining of the casting very difficult. The usual chemical analysis may not reveal this condition. The lower tin content of 88-8-4, as compared to 88-10-2, reduces this tendency on account of a smaller amount of the alpha-delta eutectoid being present and consequently less chance for inverse segregation or liquation.

Gun metal is an excellent steam and structural bronze which may be used for expansion joints, pipe fittings, gears, bolts, nuts, valves, pump pistons, castings, bushings, bearings, and, in general where strength and resistance to salt water corrosion are required. It is extensively used in naval and other marine work.

Composition—Uniform composition and freedom from impurities are essential in obtaining maximum mechanical properties and consistent service. Where the best properties are desired, the alloy should conform to the following range of elements, which is not a specification but an ideal practical manufacturing range of composition:

Copper	87.0-89.0
Tin	9.5-10.5
	or
	7.5- 8.5
Zinc ..	1.5- 2.5
	or
	3.5- 4.5
Lead	0.30 max.
Iron	0.10 max.
Nickel	0.75 max.
Phosphorus	0.05 max.
Sulphur	0.05 max.
Antimony	0.25 max.
Aluminum	None
Other elements.....	0.15 max.

Effect of Major Constituents—Increase of tin will cause an increase of the amount of the delta constituent, which will result in increased hardness and stiffness of the alloy. An increase of zinc tends also to increase the hardness and stiffness, but to a much smaller extent than an increase of tin.

Effect of Minor Constituents

Lead—Seldom, if ever, does lead add strength to a copper alloy. On the contrary, it generally detracts from the strength and its action on gun metal is no exception to this fact. Hardness is also reduced by the addition of lead, but machinability is improved by a very small amount of this metal. One-half per cent lead will make gun metal free cutting, but it is better practice to keep the lead content below this figure in foundry production, because of the liability of exceeding this amount

*Metallurgist, U. S. Naval Gun Factory, Navy Yard, Washington, D. C.

by the pyramiding of the lead content by the re-use of scrap. Lead over 0.50% does not give proportional improvement in the machinability. One-half per cent lead will also prevent checks or cracks at the junction of a boss and the body of the casting when a sufficient fillet has not been provided. In a case of this kind it would aid in pressure tightness.

Iron—Iron will increase the hardness and is especially objectionable on account of its tendency to produce hard spots which increase the difficulty of machining.

Nickel—A small amount of nickel has a tendency to decrease the grain size and its presence is beneficial rather than detrimental to the casting properties of the metal, and does not adversely affect the resistance to corrosion or wear. In the case of 88-10-2, 0.50% of lead may reduce the hardness. Three-quarters of a per cent of nickel will not materially affect the hardness. One-half per cent lead with 0.75% nickel has a tendency to maintain the normal hardness of 88-10-2 with the increased machinability due to lead. Nickel is not generally added to 88-10-2.

As 88-8-4 is normally somewhat softer than 88-10-2, an addition of 0.50% lead is not likely to affect its hardness, although it will act to increase the machinability. An addition of 0.75% nickel has a tendency to increase the hardness to that of 88-10-2 without materially affecting the casting properties or machinability. This small amount of nickel is also apt to increase the tensile strength and to increase slightly the elastic properties of 88-8-4. One-half per cent lead plus 0.75% nickel tends to increase machinability without loss of the increased hardness due to nickel. It is common practice to add from 0.50-0.75% nickel to 88-8-4.

Phosphorus—It is common practice to add a little phosphorus to gun metal for the purpose of "deoxidizing" the metal. But this practice should not be overdone because phosphorus has a greater effect on increasing the freezing range of this alloy than any other usual addition. It is difficult to produce good sound sand castings from an alloy with increased or varying amounts of phosphorus causing an increased or uncertain freezing range. No more than 0.05% of phosphorus should be added. Also, above this figure phosphorus is apt to cause the appearance of free Cu_3P with a reduction in mechanical properties and will result in poorer surface appearance and increase cleaning costs.

Sulphur—While there is little definite information on the effect of sulphur, it is generally considered doubtful practice to permit this impurity to exceed 0.05%, if the best results are desired.

Antimony—Antimony, while undesirable and never deliberately added to this alloy, will ordinarily cause no trouble if kept below 0.25%.

Aluminum—The presence of aluminum is very objectionable and it should be most rigorously excluded. During the melting of gun metal contaminated with aluminum the aluminum forms an oxide which is insoluble and results in alumina inclusions being trapped in the finished castings. Even a trace of aluminum will cause the castings to have a white silvery skin on their surfaces and its presence is fatal to castings requiring pressure tests.

Other Elements—If other elements including arsenic do not exceed 0.15%, no harmful effects can be attributed to their presence.

Physical and Mechanical Properties—The cast to shape test bar shown in Fig. 1 was employed in determining the properties in tension. Machined tension specimens were of usual form: 0.375 in. radius, 0.505 in. dia. by 2 in. gage length. The ends were threaded and screwed into self aligning fixtures to prevent displacement of Ewing extensometer while determining the elastic properties. Electrical resistivity was determined on these machine specimens prior to making the mechanical tests.

Physical Properties 88-10-2 and 88-8-4

Specific gravity.....	8.5-8.8
Weight per cu. in., lb. (approximate).....	0.314
Patternmaker's shrinkage in. per ft.....	0.15
Pouring temperature (1950°F. Ideal).....	1950-2200°F.
Electrical resistivity (approximate) 88-10-2.....	15.5
88-8-4	13.5

Electrical resistivity as referred to is the resistance, expressed in millionths of an ohm, between opposite faces of a 1 cm. tube of the material. In these units copper has a resistivity of 1.72 at 68°F.

Mechanical Properties

88-10-2 and 88-8-4

Ultimate tensile strength, psi.....	30,000- 45,000
Elastic limit, psi.....	11,000- 14,000
Modulus of elasticity.....	15,000,000
Proportional limit, psi.....	11,000- 14,000
Proof stress, psi.....	13,000- 15,000
Yield point by extensometer, psi.....	18,000- 21,000
Elongation, % in 2 in.....	15-40
Compression of 0.001 in., psi.....	16,000- 17,000
Compression of 0.01 in., psi.....	21,000- 23,000
Compression of 0.1 in., psi.....	41,000- 47,000
Compression of 0.25 in., psi.....	85,000- 97,000
Compression of 0.27-0.29 in., psi.....	100,000
First indication of rupture, psi.....	200,000-300,000
Resistance to impact (Isod), ft.-lb.....	7-14
Brinell hardness number (10 mm. ball, 500 kg. load, held 30 sec.) 88-10-2.....	60-80
88-8-4.....	50-70

Elastic limit was determined as the stress which produced a permanent elongation of 0.00006 in. in 2 in. after the load was released.

Proportional limit was obtained by applying the load in uniform increments of 400 pounds (2,000 psi.) until the elongation under stress ceased to be proportional.

Proof stress was the stress which produced a permanent elongation of exactly 0.0002 in. in 2 in. after the release of the load.

Yield point was determined by applying loads until the specimen had stretched 0.01 in. while under stress.

Compression specimens were machined, 1.129 in. dia. (1 sq.in. area) by 1 in., from 1½ in. dia. bars cast vertically in sand. Measurements were taken with a micrometer caliper, calibrated to 0.0001 in.

Specifications—The following specifications are in general use for gun metal:

A.S.T.M., B60-36.

Society of Automotive Engineers Specification, No. 62.

Federal Specification, QQ-B-691, Grades 5, 6 and 6x.

U. S. Navy Department Specification, 46-M-6.

U. S. Navy Department Specification, 46-B-5.

Federal Specification QQ-B-691, Grade 5, requires a minimum tensile strength of 40,000 psi., and a minimum elongation of 20%. The Navy Department Specification 46-M-6 conforms in technical requirements to Federal Specification QQ-B-691, Grade 5; and Navy Department Specification 46-B-5 conforms to Federal Specification QQ-B-691, Grades 6 and 6x. While the A.S.T.M., Federal, and Navy Department Specification desire 88-8-4, they nevertheless specify a range broad enough to permit the composition 88-10-2. The U. S. Army use Federal Specification QQ-B-691.

Fig. 1—Cast test bar for bronze.

an abrupt change from one section to another should be avoided by the use of

Design—Gun metal has good casting properties, but to obtain the best results with this alloy, as with other casting compositions, the design should be given very careful thought. The ideal casting should be of uniform thickness throughout at the time of pouring. When uniform cross sections are not possible,

fillets. Also, it is important to avoid excessive machine finish allowances on castings to be subjected to hydrostatic pressure. The chilling effect of the sand mold causes the gun metal casting to have a fine grained exterior, as compared with its interior. To retain this fine grained pressure tight surface, the design should maintain a cast finish for pressure castings when possible, and a minimum allowance for machine finish when machining is necessary.

Melting and Molding—This alloy may be melted in the usual type of bronze melting furnaces. Ingots may be purchased and remelted or the alloy compounded and poured into the molds from the first melting. In foundries compounding their own alloys, when difficulties are encountered or if ideal quality or the highest mechanical properties are consistently required, melting in crucibles placed in a natural draft pit type furnace is recommended. In the crucible process the copper is first melted, protected by a covering of crushed charcoal, if the copper shows indications of wildness; carbon-free manganese is added (about 1 oz. per 100 lb.); then the nickel (if desired) as 50% cupro nickel; then the tin and finally the zinc plus 0.50% for loss. If lead is desired, it should be added and stirred in well just before removing the crucible from the furnace. When phosphorus is used as a "deoxidizer," it may be added with the copper or as a final addition. A flux is not necessary. The melt is poured into cast iron pig molds; analyzed; remelted under a covering of charcoal, preferably without further additions, care being taken to prevent overheating so as not to unduly increase the zinc loss; and then poured into the castings.

Proper pouring temperature in the case of gun metal is most essential. A low pouring temperature is a great help in securing sound castings, pressure tightness and high mechanical properties. Excellent results may be obtained by pouring at 1950°F., but the actual temperature can only be obtained by trial of the particular job. Temperatures above 2200°F. are not recommended.

As gun metal is an excellent casting alloy, with a patternmaker's shrinkage of not more than 0.15 in. per ft., the usual molding practice for bronze is sufficient to secure good results. The molds may be made of either green or dry sand; green sand molds with dry sand cores are quite generally used. On larger castings the molds are frequently skin dried. Heavy sections may be chilled. With care in design, careful melting and low pouring temperature, uniformly sound castings free from defects can be consistently produced.

Test Bar—Federal Specification QQ-B-691 permits the use of either of two types of machined test bars, shown as Fig. 10 and 10A, in Federal General Specification QQ-M-151. The Webbert type is given in Fig. 10 of the specification. Fig. 10A is a modification of the Webbert type (the so-called Crown type test bar) and is very generally used. This bar differs from the Webbert type solely in the connection of the head with the test specimen. The head feeds the Webbert specimen through a web of equal thickness extending the entire length of the specimen, while in the case of the Crown type the head is connected to the ends of the specimen with no contact on the gage length. The thickness of this connecting metal is also greater in the Crown than in the Webbert proper.

The advantages of Crown type are threefold: (1) The elimination of feeding metal on the important part of the casting, in this case the gage length of the specimen; (2) better feeding of the large ends of the specimen which in turn feed the gage length; (3) ease of detaching the head without danger of bending the specimen.

The drawing of the test bar (Fig. 1) in flask gives the dimensions and manner of molding of this type of bar. The dimensions of the specimen and head are taken from Federal General Specification QQ-M-151, Fig. 10A, but as the method of molding is not specified, the molding practice generally used has been included in the drawing. The mold is made of green sand with dry sand cores, which is representative of a large percentage of castings made of this composition. When detached, the test specimens are machined to conform to the dimensions of the standard tension test specimen, 0.505 in. dia. by 2 in. gage length, shown as Type 1 in Federal General Specification for the Inspection of Metals, QQ-M-151.

Heat Treatment—Castings of this type of bronze may be heat treated to correct leakage, due to interdendritic unsoundness, in castings subjected to hydrostatic pressure test; to relieve stresses; or to improve the mechanical properties—especially ductility. The usual heat treatment consists of an anneal at 1400°F. for one hour

per inch of wall thickness (one hour per $\frac{1}{2}$ in. is preferred in some cases) followed by air cooling. Generally only pressure castings are heat treated because the mechanical properties usually specified are readily obtained without risking possible changes in dimensions by the relatively high temperature of an annealing treatment. Castings may be air cooled by opening the furnace door but to reduce distortion to a minimum they should not be removed until cooled to a moderate temperature of 500°F. or less, or they may be placed in pans and removed at the maximum temperature. Heat treatment should be done prior to machining and thus avoid dimensional discrepancies in the finished product.

The ductility of chilled cast bars can be greatly improved by heating at a temperature ranging from 1200-1400°F. for 1 hour per inch of diameter or thickness.

Welding—This type of bronze casting may be welded by the metallic arc process with bare or coated phosphor bronze electrodes. A phosphor bronze electrode of normal composition, except with a 5-7 percent tin content, gives good physical properties in the deposited metal. Such electrodes are wrought phosphor bronze which does not contain zinc. Preheating and annealing are advantageous. Gas welding may also be employed for this purpose when economy permits.

Properties of Wrought Copper-Tin-Phosphorus Alloys

(Phosphor Bronze)

By H. C. Jennison* and W. S. Girvin†

The copper-tin alloys deoxidized with phosphorus are commonly called "Phosphor Bronze". The phosphorus content varies from a trace to 0.50%. Copper and tin form a complex series of alloys but only the alpha alloys are used for wrought bronzes. The tin content varies from a fraction of 1% up to a maximum of about 11%, depending on the shape of the finished product and the physical requirements.

In sheet form the industry has standardized on three grades which have become known as Grade A, C, and D. Grade A is nominally a 4 or 5% tin alloy, while the C and D grades contain 8 and 10% tin, respectively. This series of alloys is used most extensively for springs and diaphragms because of its higher resiliency and resistance to fatigue. They also have good resistance to wear. Properties of these alloys are given in Table I.

Table I
Properties of Phosphor Bronze

	Melting ^b Point, °C.	Coefficient of Expansion, 25-300°C.	Electrical Conductivity, % I. A. C. S. at 20°C.	Thermal Conductivity ^a	Modulus of Elasticity, psi., $\times 10^{-4}$	Density lb. per cu. in.
Grade A.....	1050	0.0000178	18.37	0.195	15.0	0.320
Grade C.....	1025	0.0000182	13.00	0.150	15.0	0.318
Grade D.....	1000	0.0000183	10.6	0.121	15.0	0.317

^a = Cal. per sq. cm. per cm. per sec. per °C. at 20°C.

^b = Heycock-Neville constitution diagram.

The properties given in Tables II, III, IV, and V are from A.S.T.M. Specification—for Sheet Phosphor Bronze, Grades A, C, and D.

There are also leaded alloys in sheet form, usually containing about 5% tin and from 1-4% lead to make the alloy free cutting and for bearing purposes. Grades A, C, and D are produced in rod form. Grade A is also modified by the addition of lead. The leaded alloys are especially adapted to screw machine work. The two most common have the following nominal composition:

Copper	94%	Copper	88%
Tin	5%	Tin	4%
Lead	1%	Lead	4%
		Zinc	4%

The second alloy is usually made to meet the following physical requirements:

	Min. Tensile Strength, psi.	Min. Elongation in 2 in., %
Up to ¼ in., incl.....	60,000	25
¼-1 in., incl.....	55,000	30
Over 1 in.....	50,000	30

Grade A spring wire is made to the following requirements:

Wire Dia., in.		Tensile Strength, psi., Min.
Over	To and Including	
0.0000	0.0625	130,000
0.0625	0.1250	120,000
0.1250	0.2500	110,000
0.2500	0.3750	100,000

The wrought phosphor bronze alloys are usually cold worked but some of the lower alloys containing less than 2% of tin can be hot worked. The endurance limit of Grades A, C, and D Phosphor Bronze is approximately 25,000-27,000 psi. in the hard state. Because these alloys are refractory they take 25% addition over the regular brass tolerances for sheet and tube.

Properties of Cast Copper-Zinc-Tin-Lead Alloys

(Alloy 85-5-5-5)

By J. W. Bolton,¹ F. L. Wolf,² and Wm. Romanoff³

The alloy known as 85-5-5-5 is a copper base alloy composed of 85% copper, and 5% each of tin, zinc, and lead, plus or minus certain tolerances. Years ago it was called ounce metal, because the usual mixture was 1 oz. each of tin, zinc, and lead to each pound of copper—which roughly approximates 85-5-5-5. Today this alloy is widely known as eighty-five three fives. The derivation of this appellation is obvious.

The alloy is used for general utility purposes where reasonable strength and noncorrosive properties are demanded. It is rather widely used in the manufacture of many pressure castings, in some cases for bearings, and for miscellaneous engineering applications at temperatures not exceeding about 450°F.

The eighty-five three fives alloy is one of the most widely used nonferrous sand cast alloys. The alloy possesses the attributes of fairly low cost, good physical properties, good casting properties, and easy machinability.

The microstructure of the matrix of this alloy closely resembles that of the binary alloy of copper with 7 or 8% tin. The coring formation, characteristic in sand cast alloys of this type, is well pronounced. As a rule, the alpha-delta eutectoid is not found, or occurs only in small amounts. The characteristic cored matrix contains many small globular particles of lead. Lead is relatively insoluble in the matrix and usually is found in the dendritic fillings.

Specification—Most modern specifications for this alloy are based upon the A.S.T.M. specification B 62-36, the chemical and physical requirements of which are:

	Desired	Min.	Max.
Copper, %	85.00	84.00	86.00
Tin, %	5.00	4.00	6.00
Lead, %	5.00	4.00	6.00
Zinc, %	5.00	4.00	6.00
Iron, %	0.25
Nickel, %	1.00
Phosphorus, %	0.05
Tensile strength, psi.	30,000 min
Yield point, psi.	14,000 "
Elongation in 2 in., %	20.0 "

Most 85-5-5-5 is made from refined ingot which may be purchased under A.S.T.M. specification B 30-36 Alloy Grade 4. The chemical specifications for ingot metal are different than and should not be substituted for those for castings.

The most important factors influencing the physical properties of castings made from alloys of this type are soundness and freedom from internal porosity. The underlying causes of unsoundness and the methods for correcting are subjects which are touched upon in the data sheets of the A.F.A. dealing with this alloy. *The Foundry* has published a summary of this subject in serial form in the issues of Aug. 1, Sept. 1, Oct. 1, and Nov. 1, 1930.

Effects of Major Constituents—Increase of tin increases the hardness and stiffness of the alloy. Increase of zinc also acts in this direction, but to a less degree than an increase of tin. Increase of lead gradually decreases the strength, increases machinability, and lowers elongation.

Impurities

Iron—Free iron in appreciable amounts causes hard spots. Alloyed iron, within the specification, has no pronounced effect on the alloy. High iron increases hardness very materially, particularly when not in combination or when nickel is present. In any quantity it increases the electrical resistivity.

¹Metallurgist, The Lunkenheimer Co., Cincinnati.

²Technical Supt., Ohio Brass Co., Mansfield, Ohio.

³Technical Supt., H. Kramer & Co., Chicago.

Nickel—Within the maximum specified, nickel is not detrimental. Large amounts of nickel raise the initial freezing point and may increase the sluggishness of the metal. When sufficient nickel is added the cored structure is broken up and the color of the alloy changes. It then is not 85-5-5-5 alloy, properly speaking.

Phosphorus—Phosphorus is usually employed as a deoxidizer. For this purpose not more than a trace need be retained in the final alloy. The maximum amount permitted under the specification lengthens the freezing range of the alloy and increases the fluidity an appreciable degree. Phosphorus increases the hardness and in some cases has a tendency to discolor the surface of the castings. It also increases the tendency of the castings to "burning in" and consequent rough appearance.

Aluminum—Aluminum is an extremely dangerous impurity and even a few hundredths of a per cent has a detrimental effect on the physical properties of the alloy, because it makes the castings very unsound. Aluminum apparently alters the crystallization characteristics of the alloy very markedly. Even very small amounts sometimes cause lead sweat.

Silicon—Silicon is also a dangerous impurity. As much as 0.03% is likely to produce decided unsoundness. It apparently goes into solid solution and affects the crystallization characteristics of the alloy. In leaded alloys, the tendency toward formation of dross from interaction of silicon and lead compounds is pronounced.

Sulphur—Sulphur within the amounts allowed by the specification is not likely to cause trouble. Sulphur promotes sulphide inclusions, which if not too great in amount do not seriously impair the properties of the alloy.

Antimony—Antimony up to the maximum allowed by the specification apparently does not cause trouble.

Physical Properties—The ultimate tensile strength minimum of the specification is 30,000 psi. Average foundry practice is about 33,000 psi. However, foundries maintaining rigid technical control are able to materially exceed this average.

The modulus of elasticity of this alloy must be established arbitrarily, since no exact proportional limit is apparent. At 8,000 psi. stress the apparent modulus is about 13×10^6 psi.

The yield point in the specification is given as 14,000 psi. min. stress required to produce 0.01 in. strain in a 2 in. gage length. In a sound, well made alloy this point will be found to average about 15,500 psi. However, there is a sharp "elbow" or change in curvature in the stress strain diagram somewhat above 10,000 psi. and proportional limit is about 8,000 psi.

The min. elongation in 2 in. gage is 20%. On a good sound alloy the average will be nearer 25%.

At elevated temperatures the strength while under load drops gradually until 400°F. is reached, rather rapidly from 400-500°F., and very rapidly above 500°F. Above 500°F. the drop in tensile strength is very rapid. The above suggests that this alloy, in common with others of its type, should not be used much above 450°F. unless a reasonably large safety factor is employed. Long exposure to temperatures above 450°F. causes embrittlement.

The Brinell hardness ranges from about 48-58 (500 kg. load).

Rockwell using $\frac{1}{8}$ in. ball is about 65-75.

Specific gravity of sand cast alloy at 25°C. is about 8.7. This varies according to the soundness.

Specific gravity of chill cast alloy at 20°C. is 8.9.

Weight per cu.in. 0.314 lb.

Pattern makers' shrinkage usually is taken as $\frac{1}{8}$ in. per ft.

The linear contraction 20-900°C. is 18.4×10^{-6} .

The volume shrinkage 20-900°C. is 5.5%.

The solidification shrinkage is 4.9%.

Izod test is about 9 ft.-lb. (average of several tests).

Electrical conductivity (% of annealed copper at 20°C.) 16.4.

Creep tests have shown that the 85-5-5-5 alloy is quite inferior to the A.S.T.M. B 61-36 type valve or steam bronze at 500°F. The 85-5-5-5 alloy shows rapid and continuous creep at load of 3,000 psi.¹ at temperature of 500°F. (Ref. Proceedings A.S.T.M., Vol. 35, Part II, p. 213.) There is no danger of lead sweat in this alloy within the temperature range indicated if the alloy is made properly.

¹Proc., A.S.T.M., 1935, v. 35, p. 213.

Properties of Wrought Copper-Zinc-Tin Alloys

(Admiralty Metal)

By William B. Price*

History—Admiralty metal was originally developed by the British Admiralty for use as a condenser tube material. Copper-zinc alloys which were used for condenser tubes before the inception of Admiralty metal were either Muntz metal, containing 60% copper and 40% zinc or an alloy of 70% copper and 30% zinc. Admiralty metal rapidly superseded the 70:30 mixture and also much of the Muntz metal which had been used under less severe service conditions. The consumption of this material has continued to grow since its beginning and it is now, without question, the most common of all nonferrous tube mixtures.

In recent years many special alloys have been developed and are now offered by nonferrous tube producers. These include the copper-nickel alloys, aluminum brasses and bronzes, red brasses, and modifications of Admiralty. While these materials are of great value in a great many specific installations, Admiralty metal at present continues to be in considerable demand.

Properties—The chemical composition of Admiralty metal as specified by the A.S.T.M., United States Navy, and others, is as follows:

Copper, not less than 70.00%; tin, 0.90-1.20%; lead, not over 0.075%; iron, not over 0.06%; and zinc, remainder.

Physical Properties of Admiralty Metal

	Soft	Hard
Tensile strength, psi.....	50,000 (min.)†	90,000 (min.)†
Yield strength, psi.....	23,000	88,000
Endurance limit, psi.....	15,000	
Modulus of elasticity.....	15,000,000

Melting point.....	1715°F.	934°C.

†Stress in a material at which there occurs a permanent deformation of $\frac{1}{2}\%$ on a 2 in. gage length.

The above table gives the normal commercial tensile strength limits of hard and soft Admiralty tubing. Finish annealed tubing usually will average a tensile strength of approximately 55,000 psi. or higher. Hard drawn wire can be manufactured having a tensile strength in excess of 125,000 psi.

The value of the endurance limit is an average result of tests on annealed Admiralty metal. Under combined corrosion and repeated stress, this value would be lower. Cold working raises the endurance limit of Admiralty metal and, in general, it may be stated that the stronger the material is in tension, the higher are the endurance properties.

The figure given for coefficient of expansion is taken from Scientific Paper No. 410, U. S. Bureau of Standards, and represents an average value for the given range of temperatures.

Machinability—Admiralty metal machines similar to mild steel and should be cut at speeds and feeds approximately 50% of those used for free turning leaded brass. Cutting speed should not exceed 200 surface feet per minute. High speed, steel or carbide tools are recommended.

Physical Properties at Elevated Temperatures—Fig. 1 illustrates the physical properties of Admiralty metal at elevated temperatures. Determinations were made on standard high temperature tensile test specimens machined from $\frac{3}{4}$ in. cold drawn rod. The variation in properties with increasing temperature is normal for non-leaded alpha brasses up to 800°C. At this temperature a second phase (tin-rich)

*Scovill Mfg. Co., Waterbury, Conn.

begins to separate at the grain boundaries in a molten or semimolten condition and makes the alloy "hot short". These data indicate the hot workability of the mixture and should not be used to predict its service at elevated temperatures.

Fig. 1—Properties of Admiralty metal at elevated temperatures.

Uses—Wrought Admiralty metal is made in the form of rod, wire, sheet, and tubing. The alloy is easily worked and combines ductility, malleability, and strength with a pleasing greenish yellow color and good resistance to general corrosion. Because of these desirable characteristics, it is frequently substituted for yellow brass rod, wire, or sheet. By far the greatest application of the alloy is, however, in the form of tubes and tube fittings. As such it is used in condensers, preheaters, evaporators, and air conditioning units, in contact with salt or fresh water, oil, steam and other liquids.

Specifications—Many specifications are in use to control the purchase of Admiralty metal tubing. Among these are United States Navy Spec. 44T7e, United States Federal WW-T-756 and A.S.T.M. B44-33. The latter specification is most generally used in the trade and represents the joint opinions of many producers and users.

With respect to the difference in British and American practice, namely, the use of hard drawn and finish annealed tubing, it is quite generally accepted that each type has its particular merits. The hard drawn British tubes better resist mechanical forms of attack, air impingement, and erosion. The soft American tubes better resist chemical and electrochemical forms of corrosion.

Corrosion Resistance—The problems of corrosion resistance are by nature complex. Each installation should, where possible, be treated as an individual case. In presenting a problem of tube corrosion to a tube producer no detail of the case history should be overlooked.

Bearing in mind the limitations, it can be stated that, in general, Admiralty tubing can be used with "fair to excellent" results in practically all types of industrial heat exchanging equipment in contact with circulating water, steam, or oil at operating temperatures under 500°F.

Tinning of one or both tube surfaces subject to attack frequently is of great value in improving service life of Admiralty used under adverse conditions.

Some producers claim that tubes finished with an oxidized surface are superior in corrosion resistance to those acid cleaned.

Properties of Cast Copper-Zinc-Lead-Tin Alloys

(Medium Red Brass)

By H. M. St. John*

Classification—Medium red brass alloys contain from 2-3% of tin, 7-10% of lead, 8-15% of zinc, balance copper. Alloys in this group cast well, are readily machinable, and are in general suitable for pressure work where pressures do not greatly exceed 40 or 50 psi. at temperatures not over 250°F. They are also suitable for a great variety of brass castings where it is desired to obtain a red color at low cost, and when the mechanical properties are not important. Radiator valves, low-pressure steam fittings, and low-pressure water fittings are among the products made from alloys of this general composition.

Typical Composition and Physical Properties—A typical alloy has the following composition, in per cent: Cu 77, Zn 10, Pb 10, and Sn 3. Representative physical properties¹ are as follows:

Tensile strength, psi.	27,100
Yield point, psi.	17,900
Per cent elongation in 2 in.	11.5
Brinell hardness (500 kg. 10 mm. ball)	89

A modification of this alloy with a composition in per cent of Cu 78, Zn 9, Pb 10, Sn 2.5, and Ni 0.5 has the following properties:

Tensile strength, psi.	29,000
Yield point, psi.	17,200
Per cent elongation in 2 in.	16
Brinell hardness (500 kg. 10 mm. ball)	57

In the A.S.T.M. Specification B30-36, copper-base alloys in ingot form for sand castings alloy No. 9 is listed as follows: Cu 79-80%, Sn 2.5-3.5%, Pb 6.25-7.75%, Zn 7.5-9.5%, P 0.03% max., Sb 0.25% max., Fe 0.35% max., Ni 0.50% max., S 0.08% max., Al none, Si 0.05% max., and total impurities (other than nickel) 0.50%.

It is further stated that the following properties may be expected:

Tensile strength, psi.	22,000 to 28,000
Elongation in 2 in., %	10 to 15
Brinell hardness No.	50 to 55
Pattern maker's allowance for shrinkage, in. per ft.	0.1875 (A)
Weight, lb. per cu. ft.	540

Influence of Nickel—The addition of 0.5% nickel increases the elongation, densifies the structure (so that the interior of a moderately thick section is almost as fine-grained as the part close to the outer skin), lowers the optimum pouring temperature, and improves the machinability.

The influence of nickel on the pouring temperature is pronounced and seems to increase the fluidity at temperatures close to the freezing point. The pouring range is slightly decreased due to the effect of nickel in raising the actual freezing point. Castings of moderate size and section which may best be cast at 2200-2100°F. in the unmodified alloy cast equally well at 2125-2050°F. when 0.5% nickel is included in the composition.

Machining Qualities—The machining qualities of the alloys have been compared by a drilling test in which the time required for a weighted $\frac{3}{8}$ in. drill to pass through a $\frac{3}{8}$ in. thick test block was measured and compared with the time required for a standard block of the same thickness. Ten holes were drilled in each block and the average taken. Arbitrarily assigning the value of 100 to the modified alloy (0.5% Ni), the following results were obtained as the average of a large number of tests:

Alloy Composition, %					Machinability No.
Cu	Zn	Pb	Sn	Ni	
78	9	10	2.5	0.5	100
77	10	10	3	—	108
85	5	5	5	—	145

As compared with the alloy containing 0.5% Ni, it takes 8% longer to drill a hole through a given thickness of alloy 77:10:10:3 and 45% longer through the same thickness of the alloy 85:5:5:5. The difference in machinability may be ascribed

*Supt., Brass Foundry, Crane Co., Chicago.

¹Average of six tests on an alloy made from 50% new metal and 50% re-run metal.

to the difference in tin content. The substitution of 0.5% Ni for an equal proportion of tin improves the machinability without impairing other mechanical properties.

Properties at Elevated Temperatures—Exact data with respect to properties of these alloys at elevated temperatures are lacking, but it is well known that alloys containing as much as 10% lead cannot safely be used much above 250°F. unless at higher temperatures the pressure to which they are exposed is slight. If the percentage of lead is decreased, the temperature at which the alloy can be used increases somewhat.

Resistance to Corrosion—Generally speaking, all of the alloys in this group have about the same resistance to corrosion as the 85:5:5:5 alloy. As ordinarily used, the only point of real importance is that they do not stand up well against alkaline waters.

Effect of Alloying Elements—A large number of alloys, varying in composition within the range included here, are being made by different foundries; each one seems to have its favorite. In general their properties are much the same but there is, naturally, some variation due to change in the principal constituents. Increasing the proportion of zinc hardens the alloy, slightly increases its strength and makes it more difficult to machine. Increasing the proportion of tin hardens the alloy, substantially increases both strength and yield point and makes it more difficult to machine. Increasing the proportion of nickel (to a maximum of 2.0%) toughens rather than hardens the alloy, substantially increases the strength but not the yield point and does not greatly affect the machinability. Increasing the proportion of lead above 10% is undesirable because of difficulty with lead sweat. This segregation of lead on the surface of the casting cannot be prevented by thoroughly mixing before pouring the castings, since it is caused by the separation of lead during solidification followed by extrusion of the still molten lead to the surface of the metal as a result of contraction. This is evidenced by the fact that the lead covered surfaces are almost always found on the cope of the casting.

In order to avoid sweat at a 10% lead content the tin should be held at 2.25% or above, the zinc at 6% or above. In alloys of this class nickel does not seem to have much influence on lead segregation, whereas both tin and zinc are important. If the proportion of lead is decreased below 10%, the machinability and density of the alloy are both impaired but the danger of lead sweat decreases. With such reduction in lead content the proportion of tin may also be reduced and the strength of the metal maintained by increasing the zinc.

Impurities—The principal impurities to be considered are aluminum, magnesium, silicon, iron, sulphur, antimony, and phosphorus. Aluminum is a very undesirable impurity and should be under 0.01%. Magnesium-copper is an effective deoxidizing agent, but cannot be used with safety because there must be no residue of metallic (unoxidized) magnesium in the alloy, certainly not more than 0.01%. The presence of silicon to the extent of 0.01% or more results in segregation of lead, accompanied by a weak, brittle structure with intercrystalline fissures. Iron should not exceed 0.30%, preferably 0.20%. Sulphur should be under 0.10%, preferably 0.05%. Less than 0.20% antimony has a noticeable effect on foundry brass containing 10% lead; 0.15% should be considered a maximum. Phosphorus is permissible up to 0.05%.

Corrosion Resistance of Copper and Copper-Base Alloys

By H. L. Burghoff* and N. W. Mitchell*

Metallic copper is resistant to alkaline solutions, except those containing ammonia. Its attack by mineral and organic acids is dependent largely upon the presence of an oxidizing agent in solution. Copper also resists oxidation by water vapor at high temperatures and has good resistance in general to most salt solutions. Under certain conditions, copper or copper alloys acquire a film which may be protective, but may be damaged by the high velocity of the solution or from other causes.

Copper has poor corrosion resistance to sulphur and sulphur compounds. Alloying the metal with zinc to produce brasses greatly increases the resistance to sulphur. In general, the lower the copper content of the brass, the better the resistance to sulphur compounds.

A considerable variation in corrosion resistance occurs with the change in copper content in the copper-zinc alloys (brasses). Those alloys containing less than about 80% of copper are sometimes subject to corrosion in such a manner that the zinc is selectively removed from the alloy. This phenomenon which results in the formation of porous masses or layers of copper in the article undergoing corrosion is called "dezincification."

Dezincification is encountered with corrosive water supplies in plumbing work with alloys such as Muntz metal containing 60% copper and 40% zinc, and "2 and 1" alloy containing 67% copper, 0.5% lead, and 32.5% zinc. It is particularly serious at hot water temperatures, resulting in some cases in very short life of the installation. In condenser tube applications for marine power plants and the oil industries, dezincification occurs with Admiralty brass, which contains 70% copper, 1% tin, and 29% zinc.

Dezincification is avoided by the use of alloys containing more than about 80% of copper. In plumbing work the use of red brass (85% copper 15% zinc) has entirely eliminated failures by dezincification. Red brass appears to possess the greatest general corrosion resistance of the binary copper-zinc alloys, its advantage over copper being a somewhat superior resistance to pitting.

Addition of small amounts of antimony or arsenic have been found to improve the resistance of low copper alloys to dezincification. Although arsenic inhibits dezincification of yellow brass alloys, its use frequently leads to intercrystalline corrosion. The fact that antimony improves the resistance of low copper alloys to dezincification is important in the oil industry in particular where low copper brasses are desirable for good resistance to sulphur and sulphur compounds.

The addition of tin is of lesser but still of essential benefit with regard to dezincification when added to high brass alloys. The addition of tin to Muntz metal, resulting in Naval Brass, improves the resistance of this alloy to sea water and other corrosive solutions. The addition of tin to 70-30 brass, resulting in Admiralty, gives an improvement over the binary alloy.

The accelerated corrosive action occurring in marine and seaboard power station condenser tubes is the result of high water velocity, particularly when considerable air is entrained in the cooling water. This type of attack is known as impingement attack or destructive cavitation. Impingement attack is usually characterized by deep pitting, quite frequently with the pits having the shape of a horseshoe. With the addition of about 2% of aluminum to the ordinary brass alloys, the resulting alloy will form a self-healing film resulting in good resistance to impingement attack.

The common aluminum brass alloy used in condenser tubes for resisting impingement attack contains about 76% copper, 2% aluminum, and 22% zinc. A modification of this alloy contains 82% copper, 2% aluminum, 1% tin, and 17% zinc. The modified alloy in particular has good resistance both to impingement attack and to dezincification.

The commercial copper-nickel alloys include 20% and 30% copper and the so-called nickel silver alloys contain usually 10, 12, or 18% nickel with copper contents of about 65%, and the balance zinc. The copper-nickel and nickel silver alloys have good corrosion resistant properties, including resistance to destructive cavitation or impingement attack. The cupro nickels in particular are used many

*Research Metallurgists, Chase Brass & Copper Co., Waterbury, Conn.

times when conditions are so corrosive that other copper-base alloys have failed to show the necessary resistance. In general, the resistance of this series of alloys increases slightly with the nickel content.

Copper-aluminum alloys, known as aluminum bronzes, have gained a good reputation for corrosion resistance. The commercial alloys of this series contain usually 5, 8, or 10% aluminum with the balance copper.

The tin bronzes, or as they are frequently called, phosphor bronzes, contain up to about 8% of tin with the balance copper. These alloys are used for resisting many corrosive solutions and for plaques and tablets in the form of castings which are exposed to the atmosphere. The usefulness of tin bronzes has been limited by the high cost of the alloys and by the difficulty involved in working them.

A group of alloys which has found wide use is the silicon bronze group of copper-base alloys. These contain about 3% of silicon with or without about 1% of a third element such as zinc, tin, or manganese. The usefulness of these alloys is due to the good corrosion resistance, desirable physical properties, and the ability to be readily welded. The corrosion resistance is, in general, equal or somewhat superior to that of pure copper; for many solutions they are markedly superior.

There have been some failures of silicon bronze in a steam atmosphere under conditions of stress. There is, however, no evidence indicating that in the absence of stress the silicon bronzes are appreciably attacked by water vapor or steam. At the present time, however, the use of silicon bronzes in steam atmosphere under high stress is not recommended. A study of the effect of steam on stressed silicon bronzes is now being carried out and the data are at present quite incomplete. It is expected that considerable additional information will be available after some of these studies are completed.

Polishing of Copper and Its Alloys for Metallographic Examination

By C. H. Davis*

Location of Test Pieces

Castings—Prepare any section, preferably $\frac{1}{2}$ in. square by $\frac{1}{4}$ in. thick, by polishing the face that is normal to the side of the casting, or in the region of defects. To avoid tearing the cloth on the wheels, bevel the edges of the face of the specimen except where they are to be examined.

(a) In the case of cast copper ingots and wire bars, the uniform practice is to go 1 in. below the "set" and 1 in. in from a side or end. Such points reveal an average distribution of cuprous oxide.

(b) Sections of alloy castings to be subsequently wrought should be taken below the cropping cut at the gate end so as to reveal unsoundness. Shrinkage cavities, cold shuts, and other defects may be searched for at any point, particularly under risers and at heavy sections of sand castings. Complete sections for microscopic examination may be prepared by sawing and grinding, or by finishing the desired surface with a very sharp-pointed tool on a shaper.

Wrought Copper and Copper Alloys—For the estimation of grain size or amount of cold working of sheet metal, polish below and parallel to the surface; though if desired, one may standardize upon a lengthwise section normal to the surface. In the case of rods, wire, tubes, and other drawn material, prepare a longitudinal section either from the center to the very surface, or at points thereon. Transverse sections reveal seams, pipes, and cracks if present.

Manufactured Articles—Examine in such a way as to reveal the grain size and amount of deformation of the original metal and the history of manufacturing operations as fully as possible. For instance, in the case of cartridge shells, prepare a complete longitudinal section from base to rim.

Mounting—When delicate measurements are to be made or the edges of cross sections carefully studied, the specimens are electro-plated with copper or with nickel followed by copper. Thin sections should be mounted singly or in packs in low melting point alloys or in other media, such as plaster of Paris, sulphur, sealing wax, Bakelite, or litharge and glycerine. There is usually a difference in solution pressure between the specimen and the mounting material in certain reagents. Therefore a proper selection must be made, for instance, lead-tin alloys for brasses which are to be etched in ammonia plus H_2O_2 , while Bakelite may be employed for electrolytic etching.

A hydraulic mounting press is convenient for mounting specimens in Bakelite or the clear transparent Pontalite. The low curing temperature makes them excellent mounting media for specimens where higher temperatures would be injurious. Black Bakelite cures at 135°C . under 2500 pounds pressure, also as low as 90°C . at 2500 pounds pressure; Pontalite at 120°C . under 4000 pounds pressure.

Polishing—To obliterate saw marks or to get to the average structural condition below the surface, file the specimen carefully, but omit this operation when the surface only is to be studied. Avoid straining the metal. In the case of hard alloys it is often quicker to use an emery wheel with a copious supply of water. Grades of the finer emery cloths may be employed after filing, though this step is not essential.

The specimen is then applied to the polishing wheels which may be either vertical or horizontal, and move at velocities usually ranging from 1000-1800 r.p.m. though speeds up to 3300 r.p.m. are successfully used. There should be no appreciable vibration, a requirement best met perhaps by having a ball bearing vertical shaft motor for each horizontal wheel. Variable speeds may be secured by the use of a rheostat. Automatic polishing devices and special holders or clamps for specimens may be employed.

In order that the cloths may wear evenly, the specimen is moved constantly from center to edge of the wheel. The position on each wheel is changed so as to polish across the scratches made by the previous operation. On the last wheel a

*Ass't. Technical Manager, The American Brass Co., Waterbury, Conn.

rotary motion is given to the specimen to prevent the tailing out of any pits in the metal.

The first polishing wheel is covered with 8-12 oz. canvas duck. The abrasive may be FF Turkish emery, No. 500 carborundum, or powdered alundum. Dripping water keeps the wheel wet. The second wheel is covered with a wool broadcloth and is also kept wet. The abrasive is tripoli. (Two felt covered wheels may be used for the intermediate stage. A good felt retains the emery better than broadcloth. The grades used are first "RF" flour, then "SF 6X" flour emery.) The final wheel may be covered with a fine grade of wool broadcloth, or a selected material of soft nap often known as "kitten's ear". Chamols has also been used. Levigated alumina suspended in water is applied to this final wheel, and the cloth is kept wet with dripping water. Finely powdered magnesia is sometimes used and is applied as a dry powder, but the cloth on which magnesia is used must not be left exposed to the air for long periods because of the formation of carbonate particles. When through, the cloth should be removed from the wheel and kept moist in water containing a little hydrochloric acid. Another polishing powder is jeweler's rouge which may be applied as a thin paste and the wheel just moistened with water.

The specimens are kept wet and thoroughly rinsed free from abrasives between steps. They may be removed wet from the final wheel and immediately etched, or may be dried quickly after an alcohol rinse. When using rouge for the final polish, it is possible to take the specimens from the wheel at the critical moment when the polished face becomes clean and dry. Such a specimen is ready for etching. Pure copper is more difficult to polish than its alloys, especially since a perfect surface is required to detect the presence of cuprous oxide in the unetched specimen.

Generally speaking, an unknown specimen should be examined under the microscope before etching in order to detect flaws, oxides, soft or hard constituents, and insoluble elements, such as lead in brasses. These details may be lost or masked by etching. Variations in the practice of polishing are frequently met with and extreme care is not always necessary to accomplish the desired end.

Etching of Copper and Its Alloys for Macroscopic and Metallographic Examination

By C. H. Davis*

Etching for Macroscopic Examination—For macroscopic examination the surface may be prepared by grinding and rough polishing or by cutting with a fine tool on a shaper. The chromic acid, ferric chloride, nitric acid, or potassium bichromate reagents as given in the table may be used for etching copper, brass, bronze, copper-nickel-zinc mixtures and other alloys. The specimens may be partially immersed in the solution or the prepared surface may be swabbed with cotton dipped into the reagent. If specimens are porous, drying must be carefully accomplished, using alcohol and at times ether following the water rinse. To preserve the surface temporarily for photographing, the specimen may be covered with a thin film of colorless mineral oil, glycerine, or for permanent preservation, with a thin clear lacquer.

Etching for Microscopic Examination—Forceps having a firm spring and made of nickel-silver or phosphor bronze wire are used to hold all small samples. Platinum tips are silver soldered on these forceps if they are to be used with highly corrosive reagents. The reagent is poured into a watch glass so that the specimen may be easily agitated. A stream of running water should be close at hand. Usually one specimen only is etched at a time, but where many of the same composition and hardness are to be prepared, it is sometimes possible to etch a large number by using a potassium bichromate, ferric chloride, or copper-ammonium chloride reagent, because the action can be closely controlled.

The reagent generally employed in etching copper, alpha brass, and many other copper alloys is ammonia plus hydrogen peroxide. The proportions vary with the copper content. For instance, for pure copper five parts each of ammonium hydroxide (0.88 sp.gr.) and of water, and two parts of 9% (30 volume) hydrogen peroxide; for brass (65% copper), five parts each of ammonium hydroxide and water, and one part of 9% hydrogen peroxide. Pure beta brass may be etched with the last mixture, but alpha plus beta structures are etched first as for yellow brass, then in ferric chloride if one desires to darken the beta. Copper-ammonium chloride may be used in a similar manner, and is especially good for coloring large areas of beta.

A combination of etches must often be used to secure contrasts or the correct coloration of two or more constituents. A beautiful coloration of copper and phosphor bronze can be obtained by following an ammonia-peroxide etching with a few seconds of electrolytic etching. In this case the etched surface must not be swabbed, but should be dried quickly by alcohol, or hot air blast.

The potassium bichromate reagent is not only convenient, but etches alloys of manganese, beryllium, silicon, and other elements with copper that may not be well etched in any other manner. This reagent is also excellent for leaded brass rods, Tobin bronze, pure copper, and the nickel alloys. When beta in brass is to be darkened or a deeper contrast is desired on copper-manganese-silicon or copper-tin alloys, the potassium bichromate etch may be followed by a weak Grard's solution. Copper and beryllium-copper alloys may be first slightly etched in potassium bichromate solution and then placed for 10-15 sec. in the American Brass Co.'s formula, electrolysis solution.

The polish attack method of etching is advocated by many and is widely used. Hudson, Desch, and Pulsifer, among others, have given detailed accounts of procedure with such reagents as ammonia and its compounds.

The time required for etching increases with the amount of annealing received by the material, and decreases with the amount of cold working. The reagents given in the table generally etch well in less than one minute. Some electrolytic etching may require several minutes.

Hardeners for Copper and Copper Alloys

By Dr. G. H. Clamer*

General—The term "hardeners" is used in the industry to denote alloys employed to simplify introduction of other metals into molten copper or copper alloys; moderate amounts of these added metals do increase the hardness of copper.

Phosphor-Copper—Alloys of phosphorus with copper are manufactured chiefly in two grades containing 10 and 15% of phosphorus respectively. The approximate melting points of these two alloys are 1760 and 1870°F.

The A.S.T.M. Standard Specifications B52-27 for the chemical composition of phosphor-copper state that the material shall conform to the following requirements as to chemical composition:

	Phosphorus Min., %	Phosphorus Plus Copper Min., %	Iron Max., %
Grade A	14.0	99.75	0.15
Grade B	10.0	99.75	0.15

The above chemical compositions are also in accordance with Standard Specifications QQ-C-571 issued by the Federal Specifications Board.

Phosphor-copper may be manufactured by forcing cakes of phosphorus under the surface of molten copper and holding until the reaction ceases, or by the absorption of the phosphorus vapor by the molten copper. The first method is chiefly practiced in this country while the second process is prevalent in foreign countries. All grades of phosphor-copper are furnished as ingots in the form of notched slabs weighing from 15-20 lb. each. The alloys are brittle and can be readily broken in small pieces for weighing purposes. They are also available in shot form.

Phosphor-copper is used in the manufacture of phosphor-bronze and as a deoxidizer for zinc bronzes and other copper alloys.

In phosphor-bronzes, the phosphorus content varies from 0.05 to approximately 1.00%. The effect of phosphorus is to lower the melting point, widen the freezing range, increase shrinkage and fluidity, increase the tensile strength and resistance to compression and lower the pouring temperature of the alloy. It also has a tendency to cause the metal to eat into the sand and cores; therefore, special precautions should be taken to counteract these effects when producing sand castings.

When employed as a deoxidizer, only a small percentage of phosphor-copper is added, the purpose being to introduce only enough phosphorus to insure complete deoxidization of the metal and have no excess phosphorus remaining in the alloy. It is customary to introduce approximately 1 oz. of 15% phosphor-copper for each hundred lb. of metal to perform this function. The addition of phosphor-copper as a deoxidizer is particularly recommended for alloys such as 85-5-5-5†, 88-10-2, high lead alloys, and semi-red brass mixtures containing approximately 10% zinc. Phosphorus is usually considered an impurity in yellow brass but additions of small quantities have been recommended for deoxidizing and cleaning purposes. Not more than 1 oz. of 15% phosphor-copper per hundred lb. of metal should be used for this purpose. An excessive amount of phosphor-copper added to brass alloys containing more than 10% zinc may produce porous castings and cause wrinkle-like formations, often referred to as "spelter marks," on the surface of the castings. Where such conditions prevail, the phosphor-copper additions should be reduced.

Nickel-Copper—The principal alloy of nickel and copper contains approximately 50% nickel and has a melting point of approximately 2350°F. It dissolves readily in brass and bronze mixtures.

Nickel-copper may be produced from electrolytic nickel or from wrought monel metal. There are no standard specifications covering the composition of this prod-

*Pres., The Ajax Metal Co., Philadelphia.

†Excessive phosphorus in deoxidation of this alloy leads to low ductility. A.S.T.M. Specification B30-36 permits a maximum of 0.03% phosphorus in bronze, red brass, and semi-red brass alloys, and a maximum of 0.01% in yellow brass. Occasionally as much as 0.05% phosphorus is added. The excess above that required for deoxidation is intentionally added to produce fluidity. The excess phosphorus makes it possible to pour a greater number of molds per heat.

uct; however, the approximate composition of the resultant alloys are as follows:

	Made From Electrolytic Nickel, % Min.	Made From Wrought Monel Metal, % Min.
Nickel	50.00	50.00
Iron	0.05	1.20
Carbon	Trace	0.10
Silicon	Trace	0.05
Sulphur	Trace	Trace
Manganese	Trace	0.50
Copper	Balance	Balance

Nickel-copper can be purchased in slabs or small notched ingots weighing approximately 10 lb. each. The slabs or ingots should be thin as the alloy is somewhat difficult to break in small pieces. It can also be purchased in shot form.

Nickel-copper is used in the manufacture of nickel-silver for the addition of relatively small percentages of nickel to the common brasses and bronzes and for the improvement of leaded copper bearing alloys.

In combination with copper and zinc it imparts a white color to the metal and produces a class of alloys known as nickel-silver or German silver. The nickel content of the resultant alloys varies from approximately 5-30%.

There is evidence to support the fact that the addition of 0.50-3.00% of nickel to brass and bronze alloys will result in an increase in tensile strength, yield point, elongation, and resistance to compression, also, that some of these alloys are rendered more fluid and can be poured at lower temperatures despite the fact that the addition of nickel has been found to cause a slight increase in the melting point.

The addition of 0.50 to approximately 1.50% nickel is recommended for brass and bronze castings intended to withstand high internal pressures. Nickel additions cause a reduction in grain size and tend to produce dense, uniform fractures necessary for pressure-tight castings.

The addition of approximately 1.00% of nickel is recommended for high lead copper-base bearing alloys for the purpose of helping to hold the lead in suspension. The presence of nickel increases the rate of cooling to such an extent that the tendency towards lead sweating or segregation is reduced to a minimum.

To insure best results from nickel-copper additions to bronze alloys, special attention to deoxidization may be necessary. For this purpose, a small percentage of phosphor-copper is recommended. 1 oz. of 15% phosphor-copper per 100 lb. of metal should be sufficient to insure complete deoxidization.

Manganese-Copper—This composition is manufactured chiefly in two grades containing 25 and 30% manganese. The approximate melting points of these two alloys are 1700 and 1650°F., respectively.

Manganese-copper is produced by adding metallic manganese made by the aluminothermic process to a bath of molten copper with constant stirring and heating to prevent chilling of the copper. Both grades of manganese-copper are available in the form of ingots or notched slabs weighing approximately 10 lb. each. The slabs or ingots should be thin as the alloys are somewhat difficult to break into small pieces. They are also available in shot form.

There are no standard specifications covering the composition of these alloys; however, the approximate compositions of 25 and 30% manganese-copper produced from the above grade of metallic manganese are as follows:

	25% Grade	30% Grade
Manganese, min. %.....	25.00	30.00
Iron, max. %.....	0.60	0.75
Silicon, max. %.....	0.50	0.60
Aluminum, max. %.....	0.50	0.60
Carbon, max. %.....	0.05	0.05

Manganese-copper finds a major use in the preparation of manganese bronze; in this class of alloys the manganese content varies from 0.25% to approximately 3.50%. There is evidence to support the fact that the addition of manganese increases the tensile strength, yield point, elastic limit and hardness of these alloys with a slight lowering of elongation.

Manganese-copper is also used for deoxidizing brass and white nickel casting alloys containing lead and nickel-silver. There is evidence to show that small

amounts of manganese-copper introduced in alloys similar to 88-10-2 bronze will result in a material increase in tensile strength and elongation. Unlike phosphorus, manganese does not prevent the formation of an oxide skin on the metal during pouring. Manganese also has a tendency to reduce the fluidity of the metal. To counteract these effects, the introduction of a small percentage of phosphor-copper is recommended.

Silicon-Copper—There are various grades of silicon-copper containing from 5-50% silicon. The 10% grade is most generally used for deoxidizing purposes, while the alloy containing 50% silicon is chiefly employed in the production of copper-zinc-silicon bronzes. The melting points of the 10% and 20% grades of silicon-copper are approximately 1500 and 1650°F.

The A.S.T.M. Standard Specification B53-27 for the chemical composition of 10% silicon-copper states that the material shall conform to the following requirements as to chemical composition: Silicon, 10-12; tin, max., 0.25; zinc, max., 0.25; iron, max., 0.75; aluminum, max., 0.25; and copper, remainder. The sum of copper, silicon, and iron shall be not less than 99.4%.

This chemical composition is also in accordance with Standard Specifications QQ-C-581 issued by the Federal Specification Board.

The approximate composition of the 50% grade of silicon-copper is as follows: Silicon, 50; iron, 0.80; aluminum, 0.35; manganese, 0.05; calcium, 0.20; carbon, 0.04; other elements, 0.25; and copper, remainder.

Silicon-copper is manufactured by adding metallic silicon to a bath of molten copper with constant stirring and heating to avoid chilling of the copper. All grades of silicon-copper are available in the form of ingots or notched slabs weighing approximately 10 lb. each. The alloys are brittle and can be readily broken into small pieces for adding to molten baths.

In copper-zinc-silicon bronzes the silicon content varies from 1.00 to approximately 6.00%. The effect of silicon additions in the above amounts is to increase the tensile strength, hardness, and compressive strength in addition to increasing the fluidity of the metal. The presence of silicon also imparts greater corrosion resisting properties to these alloys and renders them admirably suitable for die castings.

Silicon-copper is particularly useful in deoxidizing nonferrous alloys that do not contain lead, such as cast monel metal and nickel-silver, and for the production of pure copper castings. In the presence of lead, the addition of silicon is harmful as it reacts with the lead and produces drossy and dirty castings. Even as little as a few hundredths of 1% produces this difficulty.

Phosphor-Tin—This alloy, used to a limited extent in the production of bronzes, is applied principally to the manufacture of white metals. It is prepared chiefly in two grades containing 3.50 and 5.00% of phosphorus. The 3.50% grade is the one most generally used. The approximate melting points of the two alloys are 925 and 975°F., respectively.

The A.S.T.M. Standard Specification B51-27 for phosphor-tin states that the material shall conform to the following requirements as to chemical composition: Phosphorus, min., 3.50%, and phosphorus plus tin, min., 99.50%.

The above chemical composition is also in accordance with Standard Specification QQ-T-351 issued by the Federal Specification Board.

Phosphor-tin may be manufactured by forcing cakes of phosphorus under the surface of molten tin and holding until the reaction ceases, or by the absorption of phosphorus vapor by the molten tin. It is believed that most of the phosphor-tin produced at the present time is made by the former method. Both grades of phosphor-tin are available in slabs weighing approximately 15 lb. each. Phosphor-tin has a white color and a metallic lustre and is extremely brittle and can be easily broken in small pieces for weighing purposes. It breaks with a coarse crystalline fracture.

As a deoxidizer for babbitt metals, only a small percentage of phosphor-tin is employed, the purpose being to add only enough phosphorus to insure complete deoxidization of the metal and have no excess phosphorus remaining in the alloy. Phosphor-tin can be used to purify babbitt metal which has become oxidized through overheating.

A small amount of phosphor-tin is advantageously added to genuine babbitts containing high percentages of copper for the purpose of increasing the fluidity thus making possible the pouring of thin linings which would otherwise be difficult because of the natural sluggishness of the molten metal.

In tinning operations where the article is dipped into molten tin and it is desirable to obtain thin and uniform coating, small additions of phosphor-tin are recommended.

Phosphor-tin is sometimes used for introducing phosphorus in the manufacture of phosphor-bronze, also for deoxidizing bronze alloys; however, its advantages for such uses do not seem to be evident in view of the fact that phosphor-copper can be used for the same purposes and at a much lower cost.

Brass Foundry Temperature Measurements

By Walter F. Graham*

Necessity for Temperature Control—A number of important advantages accrue in the brass foundry from accurate temperature control of the molten metal by means of pyrometers. First, it is often desirable in a production foundry, where physical properties of the cast metal are not particularly important, to be able to pour a maximum number of molds from a single pot in order to obtain economy of labor. The measurement and adjustment of the starting temperature will assure the foundryman that the last molds poured will contain sound, workable castings and that misruns will be eliminated. Second, the practical operation of the foundry is facilitated, in that the foundry difficulties arising from too high or too low temperature may be minimized. For example, cracks, blowholes and bad surface due to high casting temperatures and misruns, gas inclusions and cold shuts from low temperatures, may be avoided. Third, when the requirements of high strength and ductility are imposed on the foundryman, the maximum physical properties of a given alloy are developed by pouring at as low a temperature as is feasible to run the casting, assuming that the temperature is high enough to enable the liquid metal to feed out sections having a tendency to shrink.

Supplementary benefits obtained from temperature control are reduction in overheating, thereby decreasing the consumption of furnace refractories, and a minimizing of changes in composition due to volatilization of constituents of the alloys.

Pyrometric temperature control will permit the employment of semiskilled labor in handling the metal and a diversified list of alloys can be properly cast.

Effect of Pouring Temperature—High pouring temperatures in general permit excessive grain growth in the alloy during the period of the cooling of the metal in the mold. This lengthened time of cooling also permits undue segregation of impurities in the metal at the grain boundaries. The result is a lowering of the tensile strength and the ductility of the metal which has been poured at a high temperature as contrasted with better physical properties obtained in metal poured at a low temperature. Some patterns are so gated or have such sections that feeding by the pressure head of the metal in order to obtain sound sections demands metal of comparatively high temperature in order to obtain fluidity. This accounts for the belief of some foundrymen that high pouring temperatures are desirable, but it will be obvious that this consideration has nothing to do with obtaining maximum strength in castings of even section by pouring at minimum temperatures.

In obtaining the maximum physical properties it is necessary to work in a temperature range in which small variations bring about considerable effect. Therefore, close temperature control, which can only be obtained by the use of proper pyrometers, is necessary.

Methods of Temperature Measurements—As the use of the molten metal in practically all foundry operations is diversified, as regards the types of castings poured, it is, in practically all cases, necessary to measure the temperature in each individual ladle rather than in the furnace. Furthermore, it is desirable to have the temperature as nearly representative as possible of the temperature of the metal going into the mold. The system adopted may vary for different foundry conditions, but it should in every case be such that it will be flexible, and permit a quick measurement of the temperature of each ladle or crucible immediately before pouring.

In some cases it is desirable to use pyrometer equipment in the form of a portable millivolt meter which can be carried by the operator from pot to pot as the furnaces are emptied. In other cases, particularly where the metal is handled by cranes or monorail systems, it is convenient to have a millivolt meter fastened to the wall or a support adjacent to the line of travel of the ladles. As the whole matter of temperature measurements and their use is based on comparison and judgment it would seem that indicating rather than recording instruments are more adaptable to this service.

Practically all of the alloys handled in the brass foundries give off more or less fume in the ladles and for this reason optical and radiation methods of pyrometry

*Oskey Foundry Co., Philadelphia
This article was not revised for this edition.

are usually of little value. The thermo-electric system, in which there is a millivoltage generated between two dissimilar wires and in which this emf. is measured by a millivolt meter calibrated to a temperature scale, is the method generally used for brass foundry purposes.

The instrument itself should be in the middle range of resistivity as high resistance instruments of high sensitivity are too delicate to use for the rough service which may be expected in the foundry. Low resistance instruments, while rugged in their mechanical construction, are so easily affected in their reading by variations in the external resistance of the line and couplings that they are not particularly well adapted for foundry use. The instrument used should be dead beat, that is, the needle should approach the maximum point slowly without oscillation.

A potentiometer is a desirable instrument to use with the exception that the needle indication is not so easily seen by the operator as in a millivolt meter, and in addition one of the operator's hands is engaged in turning the knob to balance the instrument. The potentiometer has certain advantages over the millivolt meter in that it is not affected by variations in external resistance of the circuits.

The thermocouple or the hot ends of the wires which are immersed in the liquid metal fall into two classes; first, open end, and, second, closed end.

The open end thermocouple consists of two wires of dissimilar alloys of high melting point fastened to a handle. The operator immerses the ends of these wires 4-6 in. in the molten metal until they have each come up to the maximum temperature of the central portion of the metal in the pot. He then withdraws the wires quickly until the tips remain just under the surface of the metal and catches with his eye the maximum reading of the needle of the indicating instrument.

One reason for this manipulation is to avoid the effect of the cooler metal of the surface on the upper portion of the wires, and the reading is supposed to be taken while the tips retain the greater temperature of the metal in the central portion of the pot. The most important reason for raising the tip of an open end couple before taking the reading is to get rid of the film of oxidized metal which covers the surface of the metal between the tips. This film forms instantly after the metal has been skimmed and always has a pronounced but variable effect on the accuracy of the reading. When the tips are raised the film clings to them and is lifted from the surface of the metal with the result that momentarily there is a clear limpid metallic surface between the tips. A reading taken at this time is remarkably accurate. It is evident that this method requires a certain amount of skill in manipulation. It has, however, the advantage of requiring only two unprotected wires which are cheaper in maintenance than fabricated closed end couples. The open end tip gives a very quick reading of the temperature of the metal.

The second method, in which a closed tip is used, involves the use of a couple made by one of a number of methods. The manufacturers of various tips have claims for the advantages obtained by their particular designs, which are outside of this discussion, but in general, the most desirable one is that which gives the quickest reading. The construction of the tip must be such that the junction of the wire is protected from the alloying and corrosive action of the hot metal in order to give maximum life, but protection should be such that there is sufficient heat flow at the junction so that the maximum temperature reading will be obtained as quickly as possible. The closed type of tip may be immersed in the molten metal and the reading taken when the needle of the indicating instrument comes to rest. The construction of this type of couple protects the wires at the surface of the hot metal and prevents the error due to the lower temperature at that point. This couple is easy to manipulate and requires but little skill in handling, but the maintenance cost is higher than for the open end type.

The use of refractory tubing, which gives long life to the inclosed thermocouple, is feasible under certain circumstances where the handling conditions surrounding the use of the couple permit. Practically all nonmetallic protection tubing is fragile and in many cases considerable breakage is encountered in rough foundry usage. Metallic materials for protection tubing are satisfactory, but will eventually corrode at a shorter period than the nonmetallic refractories. Ferrous and nonferrous alloys containing nickel do not give as long life when used for protection tubing as do ferrous alloys containing high chromium.

Standardization of Pouring Temperatures—In a production foundry the pouring temperature for a given pattern can be determined by a study of the fractures and

by gaging the number of misruns obtained. The desirable temperature is the lowest pouring temperature which will give the soundest and toughest metal with the least number of misruns. The effects of small and large gates are obvious and the pouring temperatures decided upon can be raised or lowered or the gating changed in order to obtain the proper results.

After the proper pouring temperatures have been decided upon, the foundryman or pyrometer man can measure the temperatures of the metal going to the particular floor and adjust it by chilling down with gates or scrap castings.

With proper adjustment of gating, generally all patterns of certain type will fall within a given temperature range for castings of equal weight, so it becomes a relatively simple matter to dispatch metal of the proper temperature to the different foundry floors.

In the case of jobbing foundries where relatively large castings are poured, or where molding is done with loose patterns and one or two molds are set up from each pattern, the temperature of the metal is regulated and determined from previous experience with patterns and gating of a similar nature.

The maximum range of temperature encountered for the various alloys in use in the brass foundry is approximately from 1850-2350°F., depending on composition, section, and gating of the casting. The difference between correct and incorrect temperatures for any given alloy or casting may be as small as 20°F. It is obvious that this difference cannot be determined satisfactorily by the eye. The measurement of temperature of molten metal in the brass foundry by pyrometric methods leads to a greater standardization of all the foundry operations, as well as an improvement in the physical properties of the alloys cast.

Hot and Cold Working of Copper Alloys

By R. S. Pratt*

General—Plastic deformation of copper alloys is carried on in a great variety of commercial operations. All of these operations are accomplished by subjecting the material to compressive forces, although the exact nature of the application may vary considerably. The operations may be partially classified as those which are hot working operations and those which are cold working operations.

The hot working operations are those which are performed after preheating the metal to temperatures between approximately 1100°F. and 1650°F. In cold working operations the metal is not preheated above room temperature, although the operation itself may raise the temperature of the metal appreciably. Those copper alloys which are nearly pure copper are quite generally hot worked in the early stages of fabrication. The copper-zinc alloys containing appreciable quantities of the beta solid solution, that is, about 60% copper, are also hot worked commercially. There are other copper alloys which may be hot worked, but most of the commercially hot worked alloys are of the types mentioned above. The copper alloys capable of cold working cover a much wider range of analysis. Practically all of the commercial alloys may be readily cold worked within the limits of the solid solubility of the alloying elements.

In Tables I and II an effort has been made to classify the more common hot and cold working operations with respect to the performance of some of the commercial alloys in these operations. They are intended to cover the more important operations and alloys. The new proprietary alloys and precipitation hardening alloys which are in a rather different class are not covered in these tables.

The ability to either hot or cold work is affected not only by the physical properties of the metal, that is, strength and ductility, but also by the chemical characteristics of the metal and mechanical features of the operation by which the metal is to be worked. It is, therefore, difficult to predict without actual trial, whether or not a given alloy can be successfully worked in any particular operation.

Hot Working—The physical properties of a copper alloy which are required to enable it to be hot worked, are known only generally. Considerable work has been done by various investigators,^{1, 2, 4} to determine the physical properties of alloys at elevated temperatures using different tests for this purpose. The results have not been definitely consistent, particularly when viewed in respect to known results of a commercial hot working practice. Part of this difficulty has been due to the fact that different operations require different properties. Undoubtedly, if it were possible to analyze readily the forces set up in the various operations, a better understanding would be had of the properties required in the alloy. Some of the operations are involved in this respect and as a result the best way in which to determine the hot workability of an alloy in any particular operation is to try it out and learn by experience. Some progress is being made, however, as shown by the fact that many alloys can now be hot worked in operations in which they were scarcely attempted 10 or 15 years ago.

It is a generally conceded fact that the best indications of ability to be hot worked are high ductility and malleability values at high temperatures. Work has been done to determine these properties by both tensile² and compression tests⁴ or drop hammer tests.¹ Tensile strength or deformation under compressive loads as shown by these tests is directly related to the ease with which the alloys can be forged or extruded. Both these values indicate resistance to deformation which is a direct measure of the working pressures required in performing these operations. Increased working pressures mean greater wear on dies and tools, heavier equipment and greater cost. These factors, as well as ability to withstand the operations without failure, have a bearing on the commercial adaptation of the alloy to the operations involved. The success of hot working operations generally seems to depend on a fortunate combination of physical properties with respect to the particular machine in which the operation is to be performed.

One of the primary factors involved in hot working operations is the quantity of impurities in the metal. It is well known that small amounts of lead, bismuth or antimony seriously affect the workability of electrolytic copper. It is also known

N.G.—Not commercial operation.

that smaller quantities of at least some of these elements affect the hot working of the copper alloys, but there is little quantitative evidence to support the known results experienced. Tests by Bunting⁴ on brass give some data on the effect of lead and tin. The quantitative effect of the tin and lead brought out by the type of test used are not significant. In the alpha copper-zinc alloys, lead seems to develop intercrystalline weaknesses which cause some cracking. In the drop hammer test this is only shown by observation of the surface of the compressed cylinder.

In the copper-zinc alloys, hot working has generally been associated with alloys which at the higher temperatures consist largely of the beta constituent. Copper also is readily hot workable and some of the alloys containing 10% of zinc or less, have also been hot worked for some time. It is only in the last few years, however, that any appreciable amount of commercial hot working has been done on the alloys from 10-30% zinc. Undoubtedly much of the progress along this line has been made possible by the reduction in amount of lead, usually found as an impurity in the zinc. Probably the apparent hot shortness of high brass has been due to 0.04-0.05% of lead, which most of these alloys formerly contained.

A similar advancement in copper-tin alloys has been noted in the past few years, although probably for a different reason. A few years ago alloys containing more than 2% of tin were not considered hot workable. Some concerns are now hot rolling copper-tin alloys containing as much as 4% tin, although as far as is known, no other hot working operations have been successful. The advances in this alloy have been due to improvements in heating and rolling technique, rather than improvement in the purity of the alloy.

Certain of the nickel-silver alloys with copper contents of about 50% may be hot worked as well as cold worked. A paper by Price and Grant⁵ shows the range of analysis on which both hot and cold working operations may be employed. Most of the commercial alloys, however, are not readily hot worked.

Cold Working—Due to the greater amount of experience available considerably more is known about the possibilities of cold working copper alloys. As in the case of hot working, however, there is no conclusive laboratory test which is capable of predicting the action of any given alloy in all types of cold working operations. As in hot working, this is due primarily to the complicated forces to which the metal is subjected. While in general the metal is caused to flow by compressive forces, in most cases there are additional tensile forces set up locally which may cause failure.

Generally speaking, the material to be successfully cold worked must show in physical tests at room temperatures an appreciable elongation and reduction of area. Most commercial wrought copper alloys show good elongation and reduction in area test values in the annealed condition. Certainly if test values are less than about 25% elongation in 2 in. and 50% reduction in area, difficulty will be encountered in performing any appreciable amount of cold working, even of the most simple kind, such as rolling and wire drawing. Roughly the extent of drawing possible in one operation depends on the amount of elongation in the tensile test. The extent to which an alloy may be redrawn seems to vary with the reduction of area and more particularly with the degree to which the reduction of area value is reduced by each successive draw.

Despite the fact that cold working operations are compressive operations, little work has been done as yet to correlate the characteristics of laboratory compression tests to commercial operations. Laboratory compression tests are not conveniently made to give as much information of a quantitative nature as the tensile test, because of the difficulty in making them without stresses other than compression of indeterminate types and amounts. Within the past few years, however, considerable time has been spent by investigators in this connection,⁶ with particular reference to the sheet metal cupping problems.⁷ Some progress has been made but as yet there has been no unanimity of opinion as to the results obtained.

What has been said up to this point applies only to the alloy itself in its internal characteristics. Quite often these properties are normal and satisfactory, but because of surface conditions, which are of course related to the alloy, difficulties arise in cold working. The oxides of copper and zinc formed in the annealing operation cause trouble, but are readily dissolved and removed from the surface of the copper-zinc alloys by dilute sulphuric acid. In the alloys containing tin, nickel,

or silicon, the oxides formed are not so readily removed and will, unless other precautions are taken, give difficulty in commercial cold working. For many years the nickel bearing alloys have been bright or clean annealed in some way, to avoid this difficulty. With the increasing use of tin and silicon alloys similar steps will probably be found of help.

There are also many cases in which the type of lubricant used has been found to be important in the success of cold working operations. The purpose of a lubricant is to provide a film between the metal surface and the die or tool surface. A lubricant must be used which protects the surface and which even at high pressures will not permit the alloy and the die or tools to come into contact. The surface of the alloy must also be such as to hold the lubricant and not be either so smooth as to fail to hold it, or so rough as to produce stress raisers on the surface.

Impurities in the alloy are also the cause of difficulty in cold working. Of the common impurities lead and iron tend to reduce the ductility of the alloy as compared with the purer alloys. Iron raises the strength of the alloy and reduces the normal grain size produced by annealing after cold working. If these materials are present, it becomes more difficult to cold work. However, other advantages such as increased tensile strength and hardness may be obtained. Impurities such as tin have only a slight effect on the cold working of the alloy, although when present as an ingredient, it appreciably increases the strength of the alloy. Antimony and bismuth result in severe cold shortness, when present in quantities of as much as 0.01%.

Machining—As with all metals, machining operations are actually cold working operations, involving the shearing of small sections from the surface of the metal. The commercial success of this operation depends on the physical characteristics of the material to a large extent. The strength of the material affects the stress to which the cutting edge is subjected and the ductility affects the type of chip formed and the ease with which it is removed. The method of lubrication and design of tools are also important factors and they must be varied in accordance with the properties of the alloy. A small amount of lead added to the copper alloys greatly increases their machinability. The improvement is brought about by the lesser ductility of the leaded alloy. This in turn results in the chips breaking up as they leave the tool, reducing the wear on the tool and permitting the rapid removal of the chip. Alloys for machining purposes, therefore, normally contain some lead. The other alloys can be machined, but the speed and extent of the commercial operation is considerably reduced.

Machining of Copper Alloys

D. K. Crampton* and H. P. Croft†

The machining of wrought copper alloys containing over 50% copper can usually be effected by machines and tools designed for the cutting of ferrous metals, but free cutting nonferrous alloys such as the leaded brasses may be machined more rapidly than cast iron or steel and some changes in tool angles and lubricants are beneficial.

For the purpose of discussing the machining of copper alloys they may be divided roughly into the following classes.

Class I. Free or semifree cutting brasses to which some element has been added specifically to improve cutting qualities.

Class II. The straight brasses without any such additional element. These are seldom machined by the consumer to any considerable extent but present cutting problems to the producer.

Class III. The refractory bronzes, high in copper content, and containing one or more additional elements which impart high strength, hardness and toughness.

Class IV. The refractory alloys of Class III to which a moderate amount of another element has been added specifically to improve the machining properties.

Class V. Copper. Due to combination of toughness and low hardness the conditions for machining copper often differ from those suitable for Class III.

Machinability is a term not readily defined, but usually described by its effect on cutting properties and conditions of operation. Insofar as wrought copper alloys

are concerned, it is more dependent on composition than on physical or other mechanical properties. The metal being machined must, of course, be rigid enough to stand up against the turning tool without distortion. The temper of wrought copper alloys for automatic screw machining should, accordingly, be hard, consistent with ability to withstand any other possible subsequent cold working operation such as upsetting, flanging or bending. A softer temper is conducive to more rapid drilling. Generally speaking, machinability improves considerably with increasing amounts of lead and decreases with increasing amounts of tin, silicon, aluminum, nickel, and other elements.

Fig. 1—Solid and insert tooth shapes for circular saws

It also varies with the amount of copper present, the maximum machinability in the straight brasses being attained between 56 and 63%.

Machining operations should be carried out in such a manner as to produce the part in question for the lowest over-all cost and the conditions for accomplishing this might not be those which would produce the lowest power consumption, least pressure on tool, lowest temperature generated at the tool point or other criteria by which the efficiency of machining operations are often rated. Tool manufacturers' publications have a tendency to specify operating conditions which will give long if not maximum tool life whereas economical production might often be furthered by exceeding these conditions at the expense of the tool.

Tool Angles—Clearances of 4-10° are used with copper alloys while top or back rake angles range from 0-30° depending upon the alloy. Classes III and IV should be machined with greater clearance and rake angles than Class I.

Speeds—It is customary to run free cutting brass rod at the maximum spindle speed of the screw machine. However, surface speed does not always depend upon

*Director of Research, Chase Brass & Copper Co., Inc., Waterbury, Conn. and †Chief Metallurgist, Chase Brass & Copper Co. Inc., Cleveland.

Hook angle, degrees....	5	5	20		25
Clearance angle, degrees... ..	12	12	12	12	12
Above angles vary with exact composition, machine and condition, speed, lubricant, and length of throat					
Taps for brass—commercial are satisfactory.					
Speeds—multiple spindle machines 1/4-1/2 machine speed					

Knurling and Thread Rolling—These operations are grouped together as they consist essentially of displacing metal under pressure by an indenting tool thereby differing from strictly cutting operations. Due to this inherent difference the highly leaded and consequently brittle (in shear) brasses are less suited than the semileaded or nonleaded alloys. However, it is possible to supply standard free turning brass rod in a lighter temper than "drill" which will permit the majority of thread rolling and knurling operations and still provide excellent machinability for strictly cutting operations. This temper is known as "quarter hard."

For the most severe knurling and thread rolling operations semileaded or nonleaded alloys should be used. Coarse knurls must be effected at a slower speed than fine knurls.

Knurl Tools	Class I	
	Feed, in.	
Turret on	0.025	
off	0.050 up	
Side or swing	0.007-0.012	
Top	0.007-0.014	

For thread rolling of high brasses the blank should be turned to approximately (– 0.002 in.) the pitch diameter. The blank diameter should not vary more than 0.001 in.

*There are many other silicon bronzes available, some the subject of United States patents. The more common structural silicon bronzes contain about 3% silicon, which largely determines most physical properties of this type alloy. Instead of zinc these contain small percentages of manganese, tin, or combinations of these elements.

Physical properties depend considerably on form, size, temper draw and temperature of last anneal. The above values are for the range from soft annealed to drill temper, that is, finished with a temper draw of 15-25% reduction in area. Heavier reductions result in higher tensile strengths, yield points and hardness figures with lower elongations.

Milling—Many variables enter into milling practice but in general conditions are determined by the finish desired. The high tooth of the cutter will always leave a series of parallel ridges. For finish cuts the following conditions hold:

	I	II	Class III	IV	V
Rake angle, degrees.....	0-10	..	0-10	10-15
Clearance angle, cutters over 3 in. dia....	10-12	4-12	12-17
cutters under 3 in. dia....	6-7.5	3-6	8-9

Machinability—The relative machinabilities listed in Table I are only approximate and are based on free cutting brass rod, drill temper taken as a standard of 100. The machinabilities indicate approximately the average comparative performance which may be expected in the various operations of turning, drilling, milling, sawing, and grinding.

Spinning of Copper and Copper Alloys

By L. A. Ward*

Spinning of copper is particularly adapted to the manufacture of relatively small quantities of any given article since the necessary tools are relatively cheap when compared to those used in draw or stamp presses. Hence, trophy cups, vases, and models are frequently produced by spinning. It is also used for quantity production of articles where this method is more economical than others.

In addition to copper, there are a number of copper-base alloys which are used for spinning. These include gilding metal, commercial bronze, red brass, high brass, and nickel silver. The choice of alloy will usually depend on the color desired, but frequently the choice is also influenced by physical properties, cost, or both. The most commonly used nickel silver is the 18% nickel alloy. The most commonly used copper is electrolytic or tough pitch copper, but for some applications phosphorus deoxidized copper has been found superior while for others oxygen-free high conductivity copper has certain inherent advantages.

Nominal analyses and average physical properties of copper and copper-base alloys in the temper usually used for spinning are as follows:

Alloy	% Copper	% Zinc	% Nickel	Tensile Strength, psi.	% Elongation in 2 in.	Grain Size, mm.	Rockwell "F" Hardness
Copper	100*			32,000	45	0.030	40
Gilding metal	95	5		36,000	44	0.030	50
Commercial bronze	90	10		38,000	45	0.030	53
Red brass	85	15		42,000	47	0.030	60
Nickel silver (18%)	65	17	18	57,000	40	0.040	85
High brass	70	30		50,000	60	0.035	65

Note—The above physical properties are based on sheet 0.040 in. thick.

*Phosphorus-copper contains approximately 0.02% phosphorus.

Certain classes of articles can best be spun from special tempers.

The equipment consists of a lathe, spinning chucks, and tools. The head stock should provide speeds of 1200, 1800 and 2400 r.p.m. The lower speeds are used for large articles or thick sheets while the higher speeds are used for small articles, thin sheets, and for finishing operations such as planishing.

The chucks may be made of wood, cast iron, or steel, depending on the number of pieces to be made. Because of the high pressure used in spinning, a hardened steel chuck will last much longer and be more satisfactory for quantity production and will also aid in producing a smoother surface. Where the inside surface of a spun article is to be polished, a hardened steel chuck will be found much more satisfactory.

The number of chucks necessary depends on the shape of the article to be produced and the ratio of the depth and diameter of the finished shell to the diameter of the original circle. Articles of which the side walls are perpendicular to the base are much more difficult to spin than those with sloping walls and will normally require a greater number of chucks.

Special sectional chucks are used where the mouth of the finished shell is smaller than the main body so that the chuck may be drawn from the shell after the spinning operation. At times offset rolls are used in place of sectional chucks. The advantage of this method is that the chuck does not have to be taken off for every article and thus it is possible to increase the speed of production. This method is most frequently used in conjunction with draw-press-forming of articles and is economical only for large quantity production.

The spinning tools used are usually made from carbon steel (1.1% carbon), but may be made from special alloy steel or have a special hard alloy tip. The tools are usually made from $\frac{1}{4}$ in. rod and the ends have varying shapes depending on the use such as forming, planishing, or curling. The tool itself is about 18 in. long and fitted into a wood handle of approximately the same length. Yellow laundry soap is generally used as a lubricant although heavy oil or grease is sometimes used.

The amount of reduction possible without annealing will vary considerably with

*Asst Metallurgist, Chase Brass & Copper Co., Waterbury, Conn.

the alloy, the shape of the part and the size and thickness of the blank. When heavy blanks are being spun it is impossible to give heavy reduction due to the amount of pressure necessary. Again, with thin blanks wrinkling is much more severe and troublesome on heavy reductions. Consequently, in practice, the operator is the best judge of when it is necessary to stop the operation and anneal.

Annealing should be carried out at approximately 1000°F. and is preferably done in a furnace designed for annealing copper and copper alloys. If necessary, it can be done with a blow torch, but it is much more difficult to uniformly soften an article this way, and whenever possible such a method should be avoided. After annealing, the article must be cleaned to remove the oxide or scale and this is done in a 10-15% sulphuric acid solution, usually warm, followed by rinsing in cold and hot water.

The flow of copper and copper-base alloys during spinning is regulated in the same manner as for any other metal and buckling is avoided by holding a flange on the blank during spinning. No definite rule can be given for the width of this flange, but excessive thinning will be encountered if the flange is too wide, while buckling will occur if the flange is allowed to become too narrow. There will always be some thinning during spinning and where a definite wall thickness is desired this must be taken into account.

Although mass production of copper articles is now usually carried out in presses, the art of spinning copper alloys is still practiced extensively.

The Constitution of Gold-Copper Alloys

By Dr. Oscar E. Harder*

The early use of alloys of gold with copper in the form of coins and ornaments naturally made this system one of the first to which the various scientific methods for the study of alloy systems were applied as they were introduced. Strangely enough, the true nature of these alloys was not discovered until about 1916, and even today there is still lacking complete information regarding the crystal structures of alloys of different compositions and after different thermal treatments, although the alloys of gold and copper have been the subject of numerous X-ray investigations during the past decade.

The discovery that gold-copper alloys of certain compositions respond to heat treatment has created unusual interest in this system, because the mechanism of hardening is by atomic rearrangement and does not involve the precipitation phenomenon. The practical application of heat treating alloys containing gold and copper in considerable proportions to produce tough and ductile or hard and strong products by simple processes has been of great interest to the dental, jewelry and other professions.

Fig. 1—Gold-Copper Constitution Diagram.

represented a continuous series of solid solutions with a minimum in the solidification interval at 40.5 atomic per cent of copper.

Kurnakow¹ and some of his associates had, in connection with their early investigations, noted that some of their specimens in the region of equal atomic per cent concentration showed unusual hardness values. Kurnakow, Zemczuzny, and Zasedatelev² reinvestigated the system and published their results in 1916. On

Matthiessen¹ seems to have been one of the first to investigate this system. His work related to the microstructure and electrical conductivity of wire drawn from cast alloys and was published in 1861. Alloys in this system were also studied by Roberts-Austen and Osmond² in 1896, by Heycock and Neville³ in 1897, and by Roberts-Austen and Rose⁴ in 1901. These investigators concluded that gold and copper form a continuous series of solid solutions. The freezing point curves were studied by Heycock and Neville³ and by Roberts-Austen and Rose.⁴

In 1907 Kurnakow and Zemczuzny² published the results of their careful determinations of the liquidus and solidus lines of these alloys and concluded that they represented

*Asst. Director, Battelle Memorial Institute, Columbus.

checking the liquidus and solidus lines the values were found to agree with their previously published data. These values are shown in Fig. 1.* They found, however, differences in the hardness, electrical conductivity, and other properties of the quenched and slowly cooled alloys.

As a result of an extensive series of experiments, they concluded that the system in the stable form at ordinary temperatures has two intermetallic compounds, Cu_3Au and CuAu . These compounds were found to form on slow cooling or on reheating the quenched alloys. Their work outlined the region of stability of each of these compounds and showed a good correlation between such physical properties as hardness, electrical resistance, thermal conductivity, and the proposed constitution diagram. Their hardness curves of the quenched and slowly cooled alloys are shown in Fig. 2 along with their electrical resistance curve for the quenched alloys. These investigators determined the temperature of the formation of the compounds by means of cooling curves, and later investigations have shown that there is a hysteresis effect in the formation of these compounds. Therefore, the regions outlining the existence of the compounds shown in Fig. 1 are taken from the more recent investigation by Haughton and Payne,¹⁰ which, although based on electrical conductivity measurements in which the transformations were studied both on heating and cooling, are thought to represent more nearly the equilibrium conditions.

Portevin and Durand¹¹ had started an investigation of this system at the beginning of the war, but the work was interrupted, and before it could be renewed the researches by the Russian investigators⁹ had been published. Portevin and Durand, however, pointed out that gold alloys containing 20-30% of copper by weight were often brittle and could not be cold worked, but after quenching from a temperature above which these compounds formed, the alloys could be cold worked satisfactorily.

The gold-copper system has been studied extensively in connection with various theories concerning the ability of noble metal atoms to protect baser metal atoms from corrosion. Tammann¹² referred to these alloys in his work as early as 1918.

In connection with Tammann's study^{12, 13, 14} on corrosion, he concluded that 2/8 molecular gold concentration was the minimum which prevents solution of the

Fig. 1-A—Gold-Copper Constitution Diagram with concentration in weight per cent.

*For convenience in showing the intermetallic compounds in gold-copper alloys the concentrations in Figs. 1 and 2 are plotted in atomic per cent; however, in order to make the correlation between these diagrams and the more usual methods of showing concentrations, Fig. 1-A has been included, in which the concentrations are given in weight per cent.

copper ions. With strongly oxidizing agents he found that $4/8$ molecular gold concentration was necessary to prevent corrosion. Tammann's work was all based on the assumption of regular atom distribution of the gold and copper atoms in the face-centered cubic lattice.

A more recent investigation by LeBlanc, Richter, and Schiebold¹⁸ does not confirm the application of Tammann's theory to the gold-copper alloys. They found little difference in the corrosion resistance of tempered and untempered alloys. No sharp resistance limits were found in the alloys of different atomic concentrations.

On the other hand, Graf's work^{16, 17} on single crystals tended to support Tammann's theory, except when the corrosion was at increased temperatures, which might cause atom migration. X-ray examination of some of Graf's corroded specimens showed the gold lattice only, and some of them showed "superstructures."

Bain^{19, 20} discussed the gold-copper system in connection with his papers on "The Nature of Solid Solutions", "Cored Crystals and Metallic Compounds", and "Crystal Structure of Solid Solutions".

Fig. 2—Hardness and electrical resistance of slowly-cooled and quenched gold-copper alloys.

From the results of X-ray analysis he observed that the unit parameter of the alloys was generally lower than the straight line relation between the unit parameters of gold and copper when the concentration is plotted by atomic per cent. He studied the alloys containing 25 atomic per cent of gold and suggested that the gold atoms in the slowly cooled alloy occupy half of the positions in alternate 111 planes, which he referred to as "planes of greatest symmetry".²⁰ He observed that the concentration of the gold atoms in certain planes should give some special lines corresponding to a "superstructure" composed of gold atoms in the lattice. In some of his alloys he noted faint lines, which he attributed to such a "superstructure".

Smith²¹ studied the unit parameters of a series of alloys annealed 2 hr. at 600°C. and then quenched, and found that the values were all above the straight line connecting the values for the pure metals. He was unable to prepare either of the compounds in the pure form, but observed in the slowly cooled alloys of equal atomic concentration, lines which fitted the tetragonal lattice with a c/a ratio of 0.86.

The extent of the beta field in Fig. 1 was placed at 22.5-35 atomic per cent of gold by Kurnakow, Zemczuzny, and Zasedatelev.⁹ More recent investigations by Kurna-

kow and Ageew²² placed these limits as 22-40 atomic per cent of gold. The recent investigations by Haughton and Payne¹⁰ fixed the limits of field as 17.5-36.5 atomic per cent of gold, as they are shown in Fig. 1. Kurnakow, Zemczuzny, and Zasedatelev⁹ originally established the field of existence of the delta-phase (CuAu) as 42-65 atomic per cent of gold. Kurnakow and Ageew²² placed the range at 42-70 atomic per cent of gold, while Haughton and Payne¹⁰ have placed this limit at 36.5-71 atomic per cent of gold, as shown in Fig. 1. The gamma region, which might represent Cu₃Au, was noted by Haughton and Payne¹⁰, but the character of this possible phase has not been determined.

Kurnakow, Zemczuzny, and Zasedatelev⁹ placed the maximum temperature for the formation of Cu₃Au at about 371°C. and that for CuAu at about 367°C. Borelius and his associates²³ found the $\alpha \rightleftharpoons \beta$ transformation in the 25 atomic per cent gold alloy at 382°C. on cooling and 390°C. on heating. They observed the $\alpha \rightleftharpoons \delta$ transformation, the 50 atomic per cent gold alloy, at 400°C. on cooling and at 430°C. on heating. The temperatures of these transformations, as determined by Haughton and Payne,¹⁰ are those shown in Fig. 1. These values are admittedly tentative. They estimated that the Cu₃Au transformation was

probably accurate to $\pm 3^\circ\text{C}$. Owing to the hysteresis noted in the CuAu transformation, it was considered that the values obtained on heating were more reliable and the curves were drawn accordingly, but the equilibrium temperature was considered less accurate than in the case of the Cu₃Au transformation.

With further regard to the crystal structure, there is rather general agreement that the beta-phase (CuAu) has the face-centered cubic arrangement. Some investigators have failed to show this transformation and have questioned the existence of this phase, but the more detailed investigations seem to establish its existence without question. The rate of transformation is, however, slower than in the case of the transformation from the alpha to the delta phase.

Johansson and Linde^{24, 25} have suggested that the arrangement of the atoms in Cu₃Au is face-centered cubic with the gold atoms at the corners of the cube and the copper atoms at the center of the faces. The space lattice of copper, which is face-centered cubic with a unit parameter or cube edge of 3.61 Angstrom units, is shown in Fig. 3-A, while the lattice for Cu₃Au is shown in Fig. 3-B. The lattice remains face-centered cubic, but the gold atoms of larger diameter have expanded the unit parameter to 3.75 Angstrom units. This arrangement satisfies the requirements with reference to the atomic concentration and results in a "superstructure" with concentration of the gold atoms in the 001 and 110 planes, as can be seen in Fig. 3-B. A similar atomic arrangement has been proposed by Seemann and Vogt,²⁶ who noted in certain cases superimposed structural lines.

Fig. 3—Crystal lattices of gold-copper alloys. A. Copper 100%. Face-centered cubic lattice. B. Copper 75 and gold 25 atomic per cent (Cu₃Au). Face-centered cubic lattice. C. Copper 50 and gold 50 atomic per cent (CuAu). Face-centered tetragonal or body-centered tetragonal lattice.

With reference to the crystal structure of the delta-phase (CuAu) there is a lack of complete agreement. Preston's work²⁷ on an alloy containing 51.2 atomic per cent of gold showed that an alloy thoroughly annealed at 400°C. and quenched gave the face-centered cubic lattice with a unit parameter of 3.94 Angstrom units. On specimens cooled slowly from 700°C. he observed the body-centered tetragonal lattice with "a" equal to 2.79 Angstrom units, and the axial ratio $c/a = 1.31$. This would seem to be in agreement with Masing's findings,²⁸ in which he suggests that the tetragonal lattice is formed by compressing the tetragonal group, which is present in the face-centered cubic lattice, in the direction of the "c" axis, and filling half of the planes perpendicular to the "c" axis with gold atoms. This arrangement results in a concentration of the gold atoms in the 110 and 001 planes and should result in a "superstructure".

On the other hand, Johansson and Linde^{24, 25} reported a tetragonal face-centered arrangement of the atoms in the delta-phase (CuAu) with an axial ratio of 0.926. Likewise, Gorski²⁶ found a tetragonal lattice, but without systematic distribution of the copper and gold atoms, to be the stable form below 385°C. He noted that the c/a ratio changed from 0.935 at 380°C. to 0.926 at 300°C. Dehlinger and Graf,³⁰ using electrical conductivity methods, noted the transformation in the 50 atomic per cent alloy, which they considered must be due to valence electrons.

Ohshima and Sachs³¹ studied the structure of alloys containing 49.3 atomic per cent of gold, which were quenched from 350-300°C. They noted a tetragonal lattice $a = 3.95$ Angstrom units, $c = 3.68$ Angstrom units and $c/a = 0.932$. They also noted that the axial ratio varied with the temperature. They found a similar value when single crystals were examined.

Eisenhut and Kaupp³² have studied these alloys using electron emissions from a hot cathode, and observed that the copper-gold alloys of 1:1 atomic ratio, deposited on mica from the vapor phase, developed a tetragonal structure with superstructure lines after annealing 1 min. at 225-400°C. They reported that when this alloy was heated to 450-500°C. the tetragonal structure is converted into a structure of the zinc blend or diamond type with a unit parameter of 5.40 Angstrom units.

Thus, there seems to be rather general agreement with reference to the structure of the beta-phase (CuAu), but some disagreement as to the structure of the delta-phase (CuAu). Some investigators contend that the arrangement is body-centered tetragonal with an axial ratio of about 1.31, and others that it is a face-centered tetragonal arrangement with an axial ratio of $c/a = 0.926-0.932$; these crystal units, however, are essentially equivalent. Both of these groupings can be noted in models, as was pointed out by Preston.²⁷

In both cases it is necessary to compress the original face-centered cubic lattice in the direction corresponding to the "c" axis of the tetragonal lattice. This condition is satisfactorily provided for by placing the gold atoms in alternate planes perpendicular to the "c" axis, as is shown in Fig. 3-C. In this case the resulting tetragonal unit cell contains gold atoms at the corners (gold atoms 1-8, Fig. 3-C) and at the centers of the two faces which have not been compressed, while the four faces which have been compressed will contain copper atoms. This arrangement gives a cell comprising four atoms, two of which are gold, and the remaining two are copper. The tetragonal body-centered grouping is also present in the model in which the unit cell contains a gold atom in the center and copper atoms at the corners, or vice versa. This arrangement is shown in Fig. 3-C with the gold atoms (9-3-10-4-11-9-12-8) at the corners and a copper atom in the center. Another tetragonal body-centered group is also shown with a gold atom (9) at the center and copper atoms at the corners.

It is, therefore, evident that there is no essential difference in the atomic arrangement, depending upon the system being face-centered tetragonal with a c/a ratio of about 0.93 or a body-centered tetragonal with a c/a ratio of about 1.3; perhaps the former is somewhat easier to visualize. Either arrangement will give the same symmetry and the same possible "superstructure".

The possibility of heat treating gold-copper alloys to produce certain desired physical properties was indicated by the researches of Kurnakow, Zemczuzny, and Zasedatelev⁹ in 1916, and the application of this method for controlling the properties of dental golds containing considerable amounts of copper was pointed out by the present author²³ in 1923.

It is now known that the hardening of alloys by atomic rearrangement is not unique in the gold-copper system, but that other systems, for example copper-platinum and copper-palladium, show a similar phenomenon.

Recent Progress—Since the above manuscript was prepared in 1932 there has been considerable research on metal structures and superlattices have received much attention. There does not seem to be justification for changing the material originally presented but some slight additions may be made.

Superlattices have been reviewed by Nix and Shockley and by Barrett²⁴ and these reviews supply adequate references to the literature on the subject.

The more recent researches have not materially changed the information regarding the beta phase (Cu₃Au) as represented in Fig. 1. However, the change from the random arrangement of alpha appears to be simply to an ordered arrangement. Experimental data indicate that the face-centered cubic cell has copper atoms in the faces and gold atoms at the corners. While, as mentioned above, there does not now appear to be any change in the type of lattice in the alloys corresponding to approximately the Cu₃Au composition, certain discontinuities in properties such as specific heat and electrical conductivity have been observed in the temperature range of about 250-390°C. by Sykes and Jones²⁵ and by Sykes and Evans²⁶ which are not entirely consistent with the usual theories for a simple change from random to ordered atomic arrangement.

In the case of the delta phase (Cu-Au) in Fig. 1, some new information has been obtained. Johansson and Linde²⁷ have reported not only the tetragonal lattice previously reported but have also reported on orthorhombic structure in the 53 atomic per cent gold alloy in the range of about 420-380°C. which slowly changes into the tetragonal lattice in the range of 200-380°C. These authors have also reported the orthorhombic structures in alloys containing 47-53 atomic per cent of gold rapidly cooled after annealing at 410-420°C. and in alloys containing between 36 and 47 or between 53 and 65 atomic per cent gold annealed in the temperature range of 400-200°C.

Unpublished researches by Hultgren and Tarnopol show the ordered orthorhombic lattice in the Cu-Au alloy at 400 and 390°C., the tetragonal lattice in the range of 350-300°C., and the presence of both lattices at 375°C. Hultgren and Tarnopol have obtained the orthorhombic and the duplex lattices by both heating and cooling into the selected temperatures so that their evidence seems quite convincing. Long annealing times were required to establish equilibrium conditions so that good X-ray lines were obtained. The following data from Hultgren and Tarnopol show some of their results for the 50 atomic per cent alloy:

Annealed, °C	Days Annealed	b/a ratio	b/a after 6 Months at Room Temperature
400	13	1.018	1.031
390	24	1.017	1.026
375	37	1.025	1.027

From the above data, it appears that the orthorhombic structure can be preserved at room temperature but that it undergoes a slight change in axial ratios.

This new information indicates that the region in Fig. 1 designated as delta will have to be modified to show the region of the orthorhombic lattice but the data are as yet hardly adequate for location of the areas.

If a phase change is based upon a change in lattice as the criterion, then there are phaseal modifications of the Cu-Au alloy and also for alloys ranging from about 36 to 65 atomic per cent gold. There is some indication that careful microscopic work may support the X-ray studies which have been made on the Cu-Au alloys of about equal atomic concentrations.

Constitution of Gold-Silver Alloys

By Robert H. Leach*

Native alloys of gold and silver occur in many different parts of the world and consequently were among the first metals worked by prehistoric races. The alloys are malleable and ductile. The yellow color changes to a series of light green shades as the percentage of silver is increased and at 50% silver by weight, the color is nearly white.

Gold and silver can be alloyed in all proportions to form a continuous series of solid solutions.

The early investigators of this system, W. C. Roberts-Austin and T. K. Rose,¹ C. T. Heycock and F. H. Neville,² and others determined the freezing points of different compositions and their diagrams showed a single continuous curve between the melting points of gold and silver. More recently, Raydt,³ V. Fischer,⁴ L. Sterner-Rainer,⁵ W. Broniewski and K. Wesolowski⁶ have determined the solidus and liquidus points. The constitution diagram selected is based upon the work of Broniewski and Wesolowski, and is in close agreement with that of Sterner-Rainer. Although these investigators report small differences, they are in general agreement that the solidus and liquidus curves are parallel a few degrees apart and converge near the extremities of the diagram.

Fig. 1—Constitution Diagram for Gold-Silver Alloys.

X-ray examinations show that all of the gold-silver alloys have a face-centered cubic lattice. H. Weiss⁷ made an X-ray study of the system by the powder method and found a continuous variation in lattice dimensions from pure gold to pure silver. S. Holgersson⁸ found that the variation in lattice dimensions corresponds closely to a linear function of the atomic composition. He reported 4.080 Å as the lattice constant for pure gold and 4.076 Å for silver. G. Sachs and J. Weerts⁹ determined the lattice constants over the entire range of composition. They found the value for pure gold to be 4.0700 Å, and silver 4.0776 Å, and a minimum of 4.0672 Å at 19.9 weight per cent silver. M. LeBlanc and W. Erler¹⁰ confirmed the results obtained by Sachs and Weerts; finding a parabolic variation of the lattice parameter with the composition. Their determinations, however, show the minimum at approximately 35.5 weight per cent silver instead of 19.9.

Gold Alloys

E. M. Wise*

Pure gold when annealed has a tensile strength of only 16,000-17,000 psi., a Brinell hardness of about 30, and a density of 19.3. For most industrial purposes gold is alloyed with other metals to produce a harder material of lower density and lower cost. Where silver or base metals are employed for alloying, a reduction in nobility and tarnish resistance results. Where high resistance to corrosion or a high melting point is required or other special requirements are to be met, platinum or palladium are employed as alloying elements rather than silver or base metals.

Alloys of 14 carat or above are quite resistant to nitric acid while 12 carat jewelry alloys are marginal and their behavior depends upon the major alloying elements. Ten carat alloys may be considerably attacked. This behavior of gold alloys, and analogous tests using a mixture of nitric and hydrochloric acids (aqua regia) to attack the more resistant alloys are employed for quickly judging the quality of gold articles. Comparisons are made of the behavior of a streak made by rubbing the unknown gold alloy on a corrosion resistant stone and comparing its behavior in contact with acid with that of similar streaks made with a series of alloys of known composition. Many small lots of used gold articles change hands on the basis of this test which is described in detail in the book, "Testing Precious Metals."⁴

By proper selection of the alloying elements, gold alloys of considerable range in color can be had, from the yellow of pure gold to fair reds, greens, and good whites. These colored golds are important in jewelry.

The quality of gold alloys is commonly expressed in terms of carat or fineness. The carat is the proportion of gold expressed in twenty-fourths while the fineness is the proportion of gold expressed in thousandths. Pure gold is 24 carat or 1000 fine or 100% gold, while 12 carat gold is 500 fine and contains 50% gold.

Gold is frequently employed in clad form, welded or soldered to a base metal and is then called "gold filled" or "rolled gold plate." The quality or the ratio of the weight of the gold alloy coating to the total is expressed as a fraction. For example, $\frac{1}{10}$ 12 carat "gold filled" is surfaced with a layer or layers of 12 carat (50.0% gold) gold alloy weighing 10% of the weight of the composite article, which if assayed in toto would contain 5% gold. The designation "gold filled" is limited by stamping regulations to articles in which the weight of the coating is at least $\frac{1}{20}$ of the total, while lower ratios may be stamped "rolled gold plate." In any event, a quality mark cannot be applied to articles surfaced with a gold alloy under 10 carat. For further details regarding the stamping of clad articles, reference 15 should be consulted.

Watch cases require rather substantial cladding to resist wear and the present basis for classifying such stock is to designate products surfaced with at least 0.003 in. on the outside and 0.001 in. on the inside of 10 or higher carat gold alloy as "gold filled" and to designate cases surfaced with half this thickness on the outside and none inside as "rolled gold plate."

Base metals electroplated with a gold alloy usually have a far thinner coating than provided in rolled gold plate, but methods are available for producing electroplates of the same thickness as those typical of "gold filled" stock and some use is made of this method.

Melting, Casting, and Rolling⁵.—For industrial purposes gold alloys are usually melted in clay graphite crucibles heated in a gas fired furnace although some types of electric furnaces are also employed and recently renewed interest in high frequency melting has become apparent. With gold-silver-copper alloys, charcoal is at times used as a cover to avoid oxidation although a reducing flame plus a protective cover of boric acid is generally preferable. The small amount of zinc usually present in the alloy functions as a deoxidizer but where it is inadequate about 0.05% of calcium boride may be added just before pouring. Many of the dental alloys are damaged by the trace of silicon which may be reduced from the crucible and therefore must be melted in lined crucibles. Lead, sulphur, and other impurities are very damaging to gold alloys and must be excluded by the use of very pure alloying metals and precautions in handling scrap.

The alloys to be rolled are cast by slowly pouring the metal into warmed cast iron molds lightly greased with castor oil and the ingots are pickled prior to cold

*Assistant Manager, Research Laboratory, The International Nickel Co., Inc., Bayonne, N. J.

rolling. The casting of thin and wide ingots is frequently attempted but usually leads to the production of material containing shrinks which show up later. Ingots about $\frac{1}{2}$ in. thick and up to 2 in. wide are more appropriate than thin, wide ingots.

Cold rolling presents no special problems except that adequate reductions between anneals, preferably at least 50%, must be employed with white gold to avoid fire cracking. Annealing may be carried out in a nonoxidizing atmosphere or if not, the surface may be protected with a layer of ochre and boric acid which is pickled off after annealing. Some alloys, particularly those high in copper, require rapid cooling to yield maximum ductility and are quenched in hot water after annealing. Quenching is apt to crack white golds and some other compositions are also tender.

Certain types of rings, particularly men's signets or others produced in limited quantities, are made by casting gold into molds made of very fine sand while dental castings are produced in molds made of silica bonded with plaster of Paris. The latter castings are made by the so-called "lost wax process" in which a wax model is invested in a plastic mass of plaster and silica which is permitted to harden. The mold is then heated to drive out the wax and the gold alloy is melted with a gas-air torch and forced into the preheated mold by air pressure or centrifugal force. The amount and type of silica and the preheating temperature are adjusted to provide sufficient expansion to compensate for the shrinkage of the gold to yield a casting of the same size as the original wax model.

Principal Useful Gold Alloy Systems

Gold-Silver^{1, 2}—Gold and silver form a continuous series of soft, solid solutions. The maximum strength of the annealed alloys is but 30,000 psi. The liquidus and solidus are close together and rise slowly from 960°C. at the silver end to 1063°C. at the gold end. This system is discussed in detail on page 1503. The 18 carat (75% gold) alloy has an attractive green color and is sometimes used for jewelry decoration. Further increase in silver content yields paler alloys. The 12 carat (50% gold) alloy is an unattractive greenish white which tarnishes readily. Some use has been made of the 20 and 30% gold-silver alloys for electrical contacts but their resistance to tarnish is poor. The 70% gold-6% platinum-24% silver alloy has been widely used for electrical contacts in telephone equipment and is excellent, but has been replaced by pure palladium which can be used at higher currents and is less costly.

Gold-Copper^{1, 3}—A continuous series of solid solutions is formed at high temperatures but transformations occur at low temperatures yielding ordered phases based on AuCu and AuCu₃. Copper rapidly hardens gold. The maximum strength in the annealed state is about 75,000 psi. and is found at 18 carat (75% gold). Slow cooling or aging at about 300°C. causes alloys in this vicinity to harden and become rather brittle so that it is necessary to quench or rapidly cool such alloys prior to cold working. The liquidus and solidus lie close together and pass through a minimum of 880°C. at 80% Au. Further data on the equilibrium are to be found on page 1496.

The addition of copper to gold yields alloys with a red cast and the 18 carat (75% gold) and lower carat alloys find some decorative application as red golds. The 90% gold-10% copper alloy was formerly used for coinage in a number of countries. The 12 and 14 carat gold-copper alloys containing about 6% nickel possess an attractive pink color and have been quite popular for spectacle frames.

The tarnish resistance of the gold-copper alloys is of the same order as that of the gold-silver alloys.

Gold-Nickel^{3, 4, 5, 6}—A continuous series of solid solutions is formed at high temperatures but this decomposes into gold-rich and nickel-rich solid solutions of variable composition at low temperature with consequent changes in corrosion resistance, color and hardness. The quenched solid solution alloys are quite hard. A maximum hardness of about 350 Brinell hardness is observed in the middle of the series. The liquidus and solidus pass through a minimum of 950°C. at 82.5% gold.

The addition of nickel to gold rapidly effaces the yellow color and the 75% gold-25% nickel has a pleasing white color when quenched. The color deteriorates with a further increase in nickel content. The simple binary gold-nickel alloys are not useful but derived alloys containing copper and zinc yield the white golds of commerce which had a great vogue in jewelry as platinum substitutes. The high hardness of white golds of good color and their propensity to fire crack make them difficult to work. Currently, these alloys have lost popularity to the yellow golds and to platinum and palladium for white jewelry.

Gold-Palladium¹—A continuous series of solid solutions is formed which is stable at all temperatures. All of the alloys are very ductile and the maximum strength of 50,000 psi. in the annealed state is observed in the middle of the series. The liquidus and solidus rise rapidly upon the addition of palladium to gold. This is one of the reasons for the frequent addition of palladium to complex gold alloys as most of the other alloying additions tend to depress the melting range to an undesirable extent. Palladium also markedly improves the tarnish resistance of silver and base metal content dental and jewelry alloys.

Palladium lightens the color of gold and yields a number of white alloys which are, however, less brilliant than the nickel content white golds. The corrosion resistance of the palladium golds is excellent and some use has been made of the 70-80% gold binary alloys and particularly ternary alloys containing platinum for crucibles and chemical equipment including rayon spinnerets. The 80-85% gold-palladium alloy has mechanical properties similar to those of 22 carat gold and finds use in dentistry where a white, easily worked sheet material is required.

Gold-Platinum^{2, 3}—While a continuous series of solid solutions is formed at high temperature, complicated changes occur at lower temperature which cause considerable hardening and working difficulties in alloys containing less than 70% gold unless palladium, which extends the range of useful alloys, be present. Small amounts of platinum added to gold cause little increase in hardness but amounts above 30% cause a rapid rise in hardness to above 300 Brinell hardness at 70% platinum. The liquidus and solidus rise upon the addition of platinum but do not lie close together so that marked coring, difficult to eliminate, develops on casting.

The 70% gold-30% platinum alloy has been most useful and is widely used for rayon spinnerets although the relative prices of gold and platinum are currently such as to render the use of platinum rich alloys more economical and they are being introduced.

Gold-Zinc⁴—These elements form a system somewhat analogous to that formed by copper and zinc but complicated by the formation of several ordered phases at low temperature. The simple binary alloys find no commercial use but considerable percentages of zinc are frequently present in white and low carat green golds to aid in developing the desired color and in solders where it functions to lower the melting point. About 1% zinc is present in many dental golds where it aids in deoxidation and improves the mechanical properties and aging response of certain analyses.

Gold-Silver-Copper—See also references 1, 3, 5, 7, 9, and 10. This ternary system comprises a solid solution region extending along the gold-silver and gold-copper sides plus a duplex area extending out from the eutectic on the silver-copper side. The high carat alloys are solid solutions at high temperature, but may contain an ordered phase derived from AuCu at low temperatures. The low carat alloys may contain some eutectic. The melting temperature is generally rather low while the tarnish resistance depends principally upon the gold content. At 14 carat (58.3% gold) the maximum strength (in annealed material) of 78,000 psi. is secured when equal quantities of silver and copper are present.

The dental industry has used large quantities of 22 carat (91.6% gold) plate for crowns and similar restorations while alloys containing 70-90% gold with silver and copper the principal alloying elements form the basis of cast inlay golds. Strong yellow denture golds contain 80-70% gold, together with 2-12% of platinum or palladium to improve their properties. White alloys containing substantial quantities of palladium replacing corresponding amounts of gold are now in general use. These alloys contain from 15% gold with 25% palladium to 30% gold with 15% palladium, together with small amounts of platinum, 1% zinc and silver and copper the remainder.

In the jewelry trade, 18 carat alloys will range from the hard red golds containing copper as the principal alloying element, through the yellows with roughly equal quantities of silver and copper to the greens containing silver as the principal alloying element. The strength and hardness fall steadily with an increase in silver content. At 14 carat the red golds will contain copper as the principal alloying element. As the silver content is increased and copper decreased, a series of yellow golds of various shades is produced; those containing approximately equal quantities of silver and copper possess a greenish yellow color which has become popular in recent years. Further increase in the content of silver to 30-35% with copper the remainder yields greenish alloys. The green color produced in such alloys is far less attractive than that of the 18 carat gold-silver alloy. Small

amounts of zinc added to the above tend to lighten the colors but this is generally not desired.

The introduction of a substantial percentage of zinc (from 3-15%) is useful in developing green and yellow alloys of lower carat and yields materials which are age hardenable.

The strength of the annealed 14 carat gold-silver-copper alloys reaches a maximum at about 20% copper but the melting temperature (solidus) is only about 830°C. at this point and drops slightly lower at 15% copper. For this reason the use of alloys of this type requires care to avoid damage in soldering and necessitates the use of low melting solders which may be rather easily tarnished. The introduction of small percentages of palladium raises the melting point and it has been added to 12 and 14 carat alloys for this reason and also to increase resistance to tarnish.

Dental alloys containing copper and the platinum metals as well as many of the colored jewelry golds are age hardenable. They can be softened by annealing at about 700-750°C. and quenching and hardened either by slow cooling or better by reheating for 15-30 minutes at 300-450°C. This treatment is particularly effective in increasing the elastic limit and yield point which in appropriate alloys can be raised to values in excess of 100,000 psi. Age hardening is widely employed in dentistry and is essential to develop the strength required, but although it was first applied fifteen years ago, it has not been used in jewelry manufacture as widely as it should be.

Properties of Gold-Copper-Nickel-Zinc Alloys

(White Gold)

By A. W. Peterson†

The white gold alloys may be broadly divided into two types according to use; namely, the dental golds and the jewelry alloys. The former contain a relatively large amount of the platinum group metals to develop strength, ductility and corrosion resistance, while the latter today contain practically no metals of this group.

Origin—The white gold alloys in substantially the form used today in the manufacture of jewelry originated as a measure of economic necessity near the close of the World War. White alloys had been in use for jewelry for some years in Europe, but these goods were of the platinum and palladium type. Also gold alloys using nickel and cobalt as decolorizers were slightly known in Germany in 1912.¹ But the great demand for platinum, heretofore the popular white jewelry metal, for war purposes had made the metal scarce and the price prohibitive; more than ever a substitute was desirable. After many experimental failures and successes, the production of gold alloys using nickel as a decolorizer was achieved on a commercial scale, as shown by the United States, Canadian, and British patents. These alloys became popular and have retained much of their popularity to the present day.

These alloys were first used in rings, which are cast, but today most of the white gold alloys are used in the wrought condition, and the greater portion of such material is employed in the duplex metals, such as "gold filled" and "rolled gold" plate. The principal products are watchcases, bracelets, cigarette cases, pens and pencils, and optical goods. At present the greatest demand is for optical frames, in which the colors range from an inconspicuous pink to a bluish white.

Most of the white gold alloys produced are 10, 12, and 14 karat gold, and some 18 karat. This corresponds to 10, 12, 14, and 18 parts of fine gold for every 24 parts of total alloy. The base metals used are copper, nickel, and zinc.

Constitution—The constitution of the white gold alloys of the Au-Cu-Ni-Zn class is difficult to analyze exactly due to the number of combinations of the component elements that are possible. At higher temperatures (above 700°C.) these alloys are homogeneous solid solutions, but upon slow cooling to room temperature, or by low temperature (350-400°C.) aging, complex structures are formed.^{2,3} These alterations in structure are accompanied by changes in hardness and electrical resistivity. It has been shown that these alloys respond to the usual treatments that cause precipitation hardening.² This hardening is probably a combined effect of the formation and subsequent precipitation of compounds of AuCu and AuZn, or more complex compounds, as well as the separation of solid solutions from the complex matrix.^{3,4}

Physical and Mechanical Properties—The physical and mechanical properties of the white gold alloys vary according to the karat and the changes in base metal proportions. This fact is illustrated by Table I showing the density and mechanical properties of several alloys. These alloys have been annealed for one-half hour at 705°C. and air cooled except as noted.

Technology—The white gold alloys require extreme care in the choice of raw materials and processing technique. Only pure electrolytic copper and nickel free from sulphur and carbon, and highly refined zinc, should be used in the manufacture of the base metal alloy noted below. The gold used must be of mint fineness.

Best results in melting are obtained by alloying the fine gold with a previously manufactured base metal alloy of the correct composition. The actual fusion is conducted under a heavy flux of boric acid in a gas, oil, or electric furnace, using a plumbago crucible to hold the charge. Quick melting is desirable to avoid gassing of the melt. The temperature of the metal before pouring should be such that it may be poured at a rate approximating that at which the metal solidifies in the mold; otherwise blisters will be evident in the fabricated alloy. Zinc-sodium, phosphor-copper, and calcium boride have been used advantageously as deoxidizers to avoid these gas blisters. Such substances should be added in amounts small enough to leave little of the deoxidizer as a residue in the ingot; approximately 0.10-0.20% has proven sufficient in most cases.

The molds are prepared by preheating and coating with a dressing of grease and graphite, or a heavy vegetable oil. A vertical mold to give an ingot 8 in. x 3 in. x $\frac{1}{2}$ in. is suitable.

Fabrication—After pickling and cleaning, the ingots are broken down. This part of the process is an important step in the fabrication of white golds. Heavy reductions about 0.040-0.050 in. each pass, must be used to avoid splitting during subsequent annealing. Usually the ingot is reduced 50% before the first anneal. Insufficient reductions will almost without fail manifest themselves in splitting or "fire-cracking" on annealing. Alloys low in copper content will be more susceptible to this phenomenon. This technique applies equally well to the fabrication of tubing and wire as it does to sheet or strip.

Before annealing it is essential to have a uniform stress distribution in the metal bar or sheet; this may be accomplished reasonably well by passing through the last roll until absolutely flat. Annealing is carried out at from 710-760°C. Air cooling is used successfully. It is common practice to anneal in a nonoxidizing atmosphere or to protect the surface finish with an ochre-boric acid paint. Wire is generally protected by first dipping the coils in a hot saturated boric acid solution to coat them with a protective film.

Wear and Corrosion Resistance—The resistance to wear of the white gold jewelry alloys is more or less a function of the nickel content, and hence the hardness. It does, however, vary somewhat with the karat as well.

The corrosion and tarnish resistance of the alloys are governed mostly by the karat and to a certain extent by the base metal composition. The medium karats, such as 12 and 14, show good tarnish resistance in the presence of acids, body perspiration, and sulphur compounds. However, for continued use in contact with parts of the body the 12 karat alloys are often electroplated with a higher karat gold or rhodium. The 10 karat alloys, particularly those rich in copper, are quite susceptible to attack by sulphides and nitric acid.

The type of heat treatment to which the finished alloy has been subjected has marked influence on its resistance to corrosion and tarnish. It has been found that aged alloys are attacked more readily by corrosive agents, especially in the event that precipitated phases are more base than noble.*

The Lead Industry

By F. E. Wormser*

History—Lead is one of the oldest metals known to man. Probably the earliest specimen is a figure found in the Temple of Osiris at Abydos and preserved in the British Museum. It dates from 3000 B.C.

The Pharaohs, Assyrians, and Babylonians had many uses for lead in ornamental objects and structural purposes.

In 2000 B.C. the Chinese made their first money of lead. In ancient Greece and Rome, bronze coinage contained 3-30% lead.

Perhaps the most interesting historical application of lead was its general use for water pipes by the Roman people. The pipe was made in 15 standard sizes and regular 10 ft. lengths. Many of these lead pipes, in almost perfect state of preservation, have been dug up in recent years in the ruins of Pompeii and Rome, and in England where the Romans penetrated during invasions. At Bath, England, there are old Roman baths using the same lead pipe installed by the Romans 1900 years ago. Roman lead pipe was made by folding heavy sheets of cast lead and burning the seams together.

Lead was often used for the construction of caskets beautifully decorated and inscribed. Many famous soldiers such as the Black Prince and Richard II, lie buried in leaden caskets. The resting place of Christopher Columbus in Santo Domingo is said to be a leaden casket.

Many magnificent buildings, erected in the 15th and 16th centuries, still stand under their original lead roofs. Leaden ornaments, statues, leader-heads and cisterns in a perfect state of preservation have been brought down to us today, many of them architectural gems.

Lead Minerals—Although at least 60 minerals containing lead are known to science, the lead of commerce is derived almost exclusively from one mineral, galena, the sulphide of lead. The oxides and other salts of lead are comparatively unimportant sources of supply. A list of common lead minerals follows: Galena, PbS ; cerussite, $PbCO_3$; anglesite, $PbSO_4$; crocoite, $PbCrO_4$; wulfenite, $PbMoO_4$; vanadinite, $3Pb_2(VO_4)_2 \cdot PbCl_2$; and pyromorphite, $3Pb_2(AsO_4)_2 \cdot PbCl_2$.

Lead Mining—Lead ore is mined in many countries, frequently in association with zinc ore. The United States is the most important source and contributes roughly one third of the annual world output. Then in order come Australia, Mexico, Canada, Germany, Spain and Burma. The British Empire produces about one quarter of the mined lead supply.

With the development of the flotation process for the treatment of complex lead-zinc ores, many mines are now productive where formerly it was impossible, or extremely difficult, to separate the lead and zinc from each other. The flotation process has revolutionized the concentration of lead ores, both simple and complex. It so happens that the principal lead mineral found all over the world is the sulphide galena, which lends itself especially well to treatment by flotation.

Smelting and Refining—Lead concentrates, when they leave the concentrating mill, contain upwards of 40% of lead, generally 60%. The concentrates are roasted to remove the sulphur and to agglomerate the fine flotation product which is not a physically desirable blast furnace material. The roasted sinter is charged into the top of a heated blast furnace, with suitable fluxes and coke and the resulting impure lead base bullion is shipped to the refinery for further treatment. It contains silver and gold and various impurities which have to be removed before the metal is suitable for use in industry.

In the United States the Parkes Process is widely used. Electrolytic refining is also practiced and a development of recent years, known as the Betterton Process, depending upon chlorination, has also been introduced into the United States.

The Parkes Process melts the impure lead and allows it to cool below the freezing point of copper, which crystallizes and is removed by skimming. It then passes to a reverberatory or softening furnace, where the temperature is raised and a blast of air oxidizes any antimony or arsenic present to form a skin which has to be removed. The lead then goes to desilverizing kettles where small amounts of

*Sec. Lead Industries Association New York.

zinc are added. As gold and silver have a greater affinity for zinc than for lead, these precious metals immediately leave the lead in favor of the zinc. The zinc being lighter than lead, rises to the surface and when the temperature is lowered, solidifies in a skin which is readily skimmed and subsequently treated to recover the precious metals.

Refined commercial lead of a purity of 99.99% lead is common. Pig lead is generally cast in bars weighing 80-100 lb. each. The ores of Southeastern Mo. contain too little silver for profitable desilverizing. Some of this ore contains a minute amount of copper, from 0.04-0.08%, which makes the resulting pig lead derived from it particularly desirable in the chemical industries, hence its designation as chemical lead.

Grades of Lead—Commercial grades of pig lead available to the consumer comprise: Corroding Lead, Common Lead, Chemical Lead and Antimonial Lead.

Corroding lead is the designation given to a premium grade of lead used by the "corroders" of white lead, who require a metal of exceptional purity so as to avoid discoloration of the resulting white lead.

Chemical Lead is so called because of its comparatively high resistance to corrosion by sulphuric acid and other chemicals. It finds its widest outlet in the chemical manufacturing industries. The term has been used for years to describe the undesilverized lead produced from Southeastern Mo. ores.

Antimonial Lead may contain anywhere from 1-25% antimony, with the average running between 6 and 7%. Antimonial Lead is used mainly by storage battery manufacturers.

Fig 1.—Trends in the lead industry in the United States. Imports include lead in ore, base bullion, and refined lead, exports include refined lead (Bureau of Mines, Minerals Yearbook 1937).

batteries, but the use of lead for the manufacture of white lead was also extremely important. During the depression the production of white lead and other pigments have become more important as an outlet for newly mined pig lead than the electrical uses. The table on the following page shows a comparison between the uses of lead for 1929 and 1937.

The market for lead may be classified conveniently into (1) those applications where lead is used as a chemical compound and (2) those where it is used in the metallic form either alone or allied with some other metal.

The chemical compounds most important commercially are the hydrated basic lead carbonate, commonly known as white lead, basic lead sulphate (white and blue), litharge, red lead, the lead chromates, tetraethyl lead, and lead arsenate.

In the metallic form lead finds an important outlet in building construction as both pipe and sheet, and in solder. It is also used in important alloys such as type metal, antimonial lead for storage batteries, bearing alloys, foil and col-

The A.S.T.M. Specification B29-34T includes 3 grades of virgin pig lead: Grade I, corroding lead; Grade II, chemical lead; and Grade III, common lead.

Lead Industries—The following are the sellers of primary pig lead in the United States: American Metal Co., Ltd.; American Smelting & Refining Co.; Anaconda Sales Co.; Bunker Hill & Sullivan Mining & Concentrating Co.; Eagle-Picher Lead Co.; National Lead Co.; St. Joseph Lead Co.; and United States Smelting, Refining & Mining Co.

Uses of Lead—Before 1929 lead was principally used in electrical applications such as the manufacture of lead sheathed power and telephone cable and the manufacture of storage

lapsible tubes, as a coating for other materials, as lead weights, calking lead, gaskets, seals and in many other uses.

†American Bureau of Metal Statistics, includes virgin and scrap lead.

Basic Lead Carbonate—Basic lead carbonate is the most widely used of the lead pigments and forms the basis of the highest grade paint.

Basic Lead Sulphate—Basic lead sulphate is made directly from pig lead by a volatilization process in which the molten lead is fed through an atomizing flame in the presence of sulphur gases and air. The resulting fumed pigment is collected in bag houses.

Litharge—Litharge is a monoxide of lead (PbO) produced in powder and flake forms which contains roughly 93% lead and 7% oxygen.

Red Lead—Red lead is an oxide having the formula Pb_3O_4 and is made by heating powdered litharge under carefully controlled temperatures, lower than for the manufacture of litharge.

Sheet Lead—This useful metallic lead product is rolled in widths up to 11½ ft. wide and in any thicknesses desired. Sheet lead is widely used in chemical construction, where its resistance to attack from dilute sulphuric acid makes it a valuable metal to use in many industrial processes. It is also used in building construction as a roofing material, flashing, for shower pans, X-ray proofing and sound proofing.

Lead Pipe—Lead pipe has had a long career in transporting water and chemicals. It is a metal highly favored in the plumbing industry. Lead traps are another plumbing outlet.

Soldering Alloys—One of the commonest of the lead alloys is solder. Common solder contains 50% lead and 50% tin—the half and half grade. Another grade contains 60% lead and 40% tin and is used industrially for automobile radiators and the like. Plumbers' wiping solder carries 38-42% tin, 0-2% antimony, with the balance lead.

Hard Lead (Lead-Antimony Alloys)—This is an alloy containing from 1-12% antimony. Storage battery manufacturers use great quantities of antimonial lead containing approximately 7-12% antimony and frequently ¼% tin. Antimonial lead sheet (6% antimony), is also used widely in the United States for building construction. Hard lead is also used in shrapnel and collapsible tubes.

White Metal Bearing Alloys—White metal bearing alloys vary widely in composition. A common formula of a lead base bearing alloy used in railroad cars is 87% lead, 4% tin and 9% antimony. Lead bearing bronzes contain much smaller amounts of lead and are essentially mixtures of lead, copper and tin, with a lead content of 10-20%.

Numerous alloys of lead and alkaline earth, such as calcium and sodium have been developed in recent years and are playing an increasingly important part in bearing alloys.

Type Metals—This lead alloy is made from lead, tin and antimony. Typical composition is as follows:

Type Metals (In %)

	Lead	Tin	Antimony	Copper
Electrotype metal.....	93	3	4
Linotype metal.....	85	3	12
Monotype metal.....	87-84	3-4	10-12
Stereotype metal.....	82-87	3-17	12-23	0-0.5
Type metal (small type).....	70	10	18	2

Fusible Lead Alloys—Many lead alloys are known which melt at low temperatures and which are used for electric fuses, automatic sprinkler systems and boiler plugs. Compositions will be found on page 1328 of this Handbook.

Terne Plate—Terne metal is an alloy of lead and tin used to coat black steel sheets. Terne alloy contains from 20-25% tin with the balance lead.

Lead Foil—Lead foil is generally known as composition metal foil and is made by rolling a sandwich of lead between 2 sheets of tin, the result being to produce a tight union of the metals. The composition foil used for wrapping cigarettes is generally 0.0005 in. thick.

Ammunition—Large quantities of lead are used in ammunition for both military and sporting purposes. The alloy used may contain up to 1% arsenic.

Lead Storage Batteries—Lead storage batteries furnish a large outlet for metallic lead and lead pigments. They consist of a series of plates made from antimonial lead and pasted with a mixture of litharge and red lead. The electrolyte used is sulphuric acid. The lead that is used for this purpose is generally reclaimed after the battery has ceased its useful life. During the depression lead reclaimed from old batteries became an important source of the metal, at times furnishing an amount of lead almost equivalent to that recovered from mining operations.

Constitution of Lead-Antimony Alloys

By R. S. Dean*

The lead-antimony system so far as has been definitely shown may be represented by a comparatively simple constitutional diagram. Solid solutions are formed to the extent of a few per cent at both the lead and antimony ends of the system and these two solid solutions form a eutectic of about 12% antimony. Thermal and microscopic analyses do not show any evidence of an intermetallic compound. A general diagram of the system is shown in Fig. 1. The alloys near the lead end of the diagram are of greatest practical importance. The constitution diagram for this end of the system is reproduced on a much larger scale in Fig. 2. The solubility of antimony and lead decreases according to this diagram from 2.45% at the eutectic temperature to about 0.25% at 20°C. This decrease makes possible the dispersion hardening of the alloy by appropriate treatment. The essential points in this hardening are that the alloy be heated to a temperature above the solubility curve and cooled rapidly into the zone of supersaturation. The more rapid this cooling the more rapid the hardening takes place and the greater the final hardening. The agglomeration of the dispersed antimony, (or antimony-rich solid solution) takes place in this alloy at room temperature so that the maximum hardness obtained is not permanent, but falls off somewhat with time, approaching an equilibrium value for each temperature. This agglomeration of antimony particles is markedly accelerated by cold work on the alloy, thereby causing the hardened alloys to break down under fatigue to give widened grain boundaries in which the antimony is agglomerated to comparatively large particles.

A recent investigation by Obinata and Schmid using X-ray studies indicates that the solubility at 247°C. may be as high as 2.94%. According to these investigators the lattice constant falls linearly with increased atomic per cent of antimony from 4.9389 Å units for pure lead to 4.9371 Å units for the saturated solid solution. Studies by LeBlanc and Schöpel on the electrical conductivity of lead-antimony alloys, however, confirm the value of 2.5% antimony for the solubility limit at 249°C. The exact composition of the eutectic mixture has not been agreed upon. Unquestionably it depends upon the rate of cooling. By very slow cooling Quadrat and Jiriste find the value of 11.4-11.5% antimony for the eutectic. Alloys of eutectic composition were previously reported to expand on solidification. Fogler has shown this not to be the case. Heating curves show a eutectic temperature of

Fig. 1—Lead-Antimony Constitution Diagram (Gontermann, Dean, Schumacher, and Endo).

Fig. 2—Lead-Antimony Constitution Diagram for alloys of greatest practical importance

several degrees higher than cooling, doubtless due to the agglomeration of the antimony particles. Müller has studied the electrical conductivity in the liquid state and failed to find any evidence of a compound. Near the antimony end the investigations are somewhat meager. Endo studied the magnetic susceptibility and found a solid solubility of lead and antimony amounting to 5% at 250°C. LeBlanc

*Chief Engineer, Metallurgical Div., Bureau of Mines, United States Dept. of the Interior, Washington, D. C.

and Schöpel found a solubility of lead in antimony of 3.5% at 249°C., by electrical conductivity measurement. This is not, however, confirmed by the X-ray studies of Solomon and Jones, who find that the lattice parameters of the antimony rhombohedra are identical in the pure metal and the hypereutectic antimony-lead alloys. The parameter of the lead lattice is changed, confirming the existence of solid solutions at the lead end of the system.

Hidnert has measured the thermal expansion of lead-antimony alloys from 2.9-98.0% antimony.

The earlier work on precipitation hardening in the lead-antimony system has been confirmed by H. Hanemann and his associates, who have also investigated the phenomenon of creep in these alloys. These investigators find an unusually large effect of the simultaneous presence of very small amounts of copper and arsenic on the hardness of the 1% antimony-lead alloy.

Ageew and Krotov have shown by X-ray analysis that the solid solution of antimony in lead is the simple monatomic type.

Derge, Kommel, and Mehl find that body-centered rhombohedral antimony precipitates from face-centered cubic lead as plates parallel to the [111] planes of lead.

Constitution of Lead-Bismuth Alloys

By G. O. Hiers*

The lead-bismuth alloys form a eutectiferous system and no compounds exist. The alloys are mutually soluble in the liquid state and there are three solid solutions, designated as alpha, beta, and gamma.

The Liquidus—The liquidus curve has two branches, A B C and C D which meet at the eutectic, C, at 125°C. with a composition of 54.9% bismuth.

The Solidus—The solidus curve is defined as A E F G C H D. There is a peritectic point F at 184°C. with composition 29% bismuth. The peritectic horizontal E F B extends from E at 22.5% bismuth to B at 36.5% bismuth. The eutectic horizontal G C H runs from G at 36.7% bismuth to H at approximately 99.5% bismuth.

The remaining solid solution boundary points are I at 20% bismuth, J at 25% bismuth, K at 33% bismuth and L at about 0.1% bismuth, when considered at 0°C.

Due to recent knowledge, this diagram differs from the one in the International Critical Tables in several respects, namely:

1. The peritectic point and reaction horizontal are incorporated, representing the thermodynamic studies of Strickler and Seltz.
2. The eutectic point and horizontal limits are incorporated from the work of Strickler and Seltz.
3. The solid solution boundary points I, J and K are placed from X-ray studies of Solomon and Jones.

Constitution of Lead-Cadmium Alloys

By W. A. Cowan* and G. O. Hiers†

The lead-cadmium alloys have not been thoroughly examined with respect to equilibrium constitution, particularly with regard to the possible solid solutions which may exist. From the data known the two metals are completely soluble in each other when liquid, but only partially soluble when solid and form a simple eutectiferous series.

The Liquidus—The liquidus curve ABC descends rapidly to the eutectic point of 17.4% cadmium, existing at a temperature of 249°C. The liquidus BC which leads to the cadmium end of the diagram is rather extraordinary in shape and is taken from Kapp's cooling curve results. The eutectic point has been fixed by Barlow.

The Solidus—The solidus curve AD is dotted because there is no experimental

Fig. 1—Lead-cadmium constitution diagram.

vidence to determine its shape. The curve has been drawn straight leading from the melting point of lead at 327°C. to the eutectic arrest temperature horizontal. The point D is located by the Tammann method of measurement of the eutectic interval of time. Goebel also furnished further experimental evidence of such a composition by means of density and hardness measurements of specimens quenched from the eutectic temperature.

A dotted line DF has been arbitrarily drawn to indicate the limited solubility of cadmium in lead in the solid state. Vautin, in a British patent, indefinitely suggests 2% cadmium as the limit of solid solubility at ordinary temperatures.

Di Capera was unable to discover any evidence of the solid solubility of lead in cadmium and the eutectic arrest has been drawn to intersect the 100% cadmium vertical. Guertler considers the possibility of a maximum solubility of 8% lead in cadmium at the eutectic temperature.

The area ADB represents a mixture of liquid metal and the alpha solid solution, while CBE correspondingly shows a mixture of liquid metal and solid cadmium.

Alloys within ADFH consist entirely of alpha solid solution and DFGE denotes a heterogeneous mixture of alpha solid solution and solid cadmium.

Constitution of Lead-Calcium Alloys

By Earle E. Schumacher* and G. M. Bouton*

A constitutional diagram for the system lead-calcium, constructed from thermal and microscopic data published by L. Donski¹ and N. Baar,² is given in Fig. 1. This

Fig. 1—Lead-Calcium Constitution Diagram (L. Donski and N. Baar).

Fig. 2—Curves showing peritectic modification and solid solubility at the lead end of the lead-calcium diagram.

diagram shows the system to contain 3 compounds, Pb_3Ca , $PbCa$ and $PbCa_2$, which have freezing points at 646, 928 and 1106°C., respectively, and two eutectics, one at 10% calcium and one at 58% calcium. The compound Pb_3Ca is hard and brittle and not appreciably affected by exposure to the air. The other two compounds readily disintegrate in the air, especially if any moisture is present. The existence of these compounds has been confirmed by electrode potential measurements made by Kremann, Wostall and Schöpfer³ and by studies of the

pressure coefficients of electrical resistance made by W. C. Ufford.⁴ The eutectic at 10% calcium melts at 620°C. and consists of a solid solution ($PbCa$ in Pb_3Ca) and the compound $PbCa$. The eutectic at 58% calcium melts at 700°C. and consists of a solid solution (calcium in $PbCa_2$) and calcium.

Solid solutions exist between 6.1 and 7.6% calcium and between 27.6 and 39% calcium. No solid solutions have been reported in alloys at the extreme calcium end of the system. Recent investigations of lead-rich alloys show a peritectic reaction and a slight solid solubility of calcium in lead. In Fig. 2 is shown a constitution diagram for the lead end of the system, taken from the work of Schumacher and Bouton,⁵ and based on data from thermal analyses, microscopic examination, age hardening studies, and electrical conductivity measurements. The change in solubility from 0.1% calcium at 327°C. to 0.01% at 20°C. makes possible the dispersion hardening of certain of these alloys by appropriate heat treatment.

Constitution of the Lead-Magnesium Alloys

By R. L. Dowdell* and Carrie H. Green*

Considerable work has been done on the simple lead-magnesium system. The earliest work reported on lead-magnesium is by Heycock and Neville.¹ The constitution diagram given by Hansen,² who has summarized the work well up to 1933, is shown in Fig. 1.

Fig. 1.—Lead-magnesium constitution diagram.

A summary of important data for this system is given in Table I.

Table I
Data on Constitution

	Investigators			
	Grube ³	Kurnakow and Stepanow ⁴	Abel Redlich Spausta ⁵	Lynn
Melting point, composition,				
PbMg ₂ (80.99% Pb).....	551°C.	550°C.	
Mg-PbMg ₂ eutectic temperature.....	459°C.	475°C.	470°C.	..
	average			
Mg-PbMg ₂ eutectic composition.....	67% Pb	68.05% Pb	
PbMg ₂ -Pb eutectic temperature	247°C.	253°C.	249°C	250°C.
	average	average		average
PbMg ₂ -Pb eutectic composition.....	97% Pb	97.8% Pb	97.03% Pb
				Tammann's method
Max. solubility of Mg in Pb at eutectic temperature	(Kurnakow, Pogodin, Vindusova)			
		0.7% Mg		0.85% Mg
Max. solubility of Mg in Pb at room temperature (20°C.)		0.2% Mg		< 0.249% Mg*

*Cast alloy with 0.249% Mg age hardens at room temperature from 5.4 Vickers to 9 in about one month. When quenched from 240°C. after 1½ hours and aged for 90 hours at room temperature its hardness increased from 4.6 to 5.9. This indicates the solubility of magnesium in lead is probably less than 0.1%.

*University of Minnesota, Minneapolis

Fig. 2 is an enlarged portion of the lead end of the lead-magnesium diagram by Lynn.

The compound Pb Mg_2 , (19% Mg by weight) resembles silicon in appearance on a fresh fracture, but on air exposure turns black rapidly and forms a fine black powder. The compound is exceedingly brittle and scratches glass easily. Its crystallographic structure was reported by Sacklowski,⁸ and later by Friauf,⁹ to be cubic (CaF_2 type) with a lattice parameter of 6.75 Å, with 4 molecules in the unit cell.

The effect of magnesium additions on the density of lead up to 5% magnesium is shown in Table II, together with some of their mechanical properties.

Fig. 2—Lead end of the lead-magnesium constitution diagram.

*Southeast Missouri desilverized commercial lead, purity, 99.997%.

†Magnesium of nominal purity, 99.9%.

Hanemann and Stockmeyer¹⁰ claimed that the addition of 1.0% magnesium hardened lead more than an addition of 14% antimony and that the alloy was stable in air and water and only slowly dissolved by acids. The writers,¹¹ however, find that a wrought alloy of even less than 1.0% magnesium decomposes rapidly in water, thereby dissociating water to hydrogen and hydroxyl ions. The small amount of eutectic of Mg_2Pb and alpha probably reacts galvanically with the result that the alloys fall apart even in distilled water, apparently by intergranular corrosion. Cast alloys are somewhat less active in decomposition.

Lead alloys containing 1-2% magnesium have been recommended for bird shot for waterfowl, primarily because of their fast decomposition in either water or gastric juices.

Constitution of Lead-Silver Alloys

By A. J. Dornblatt*

Binary alloys of silver and lead form no intermediate phase, are miscible in all proportions when liquid, and on freezing form an eutectiferous series of alloys exhibiting but slight solubility in the solid state.

The complete miscibility of the two metals was established by Wright.¹ The liquidus curve was established through the work of Heycock and Neville,^{2,3} Friedrich,⁴ and Petrenko.⁵ These investigators placed the eutectic temperature at 304°C. The eutectic composition, according to Heycock and Neville, is 96% lead; according to Petrenko, about 97% lead, and, according to Friedrich, it is at 97.5% lead. This latter value is probably the most reliable. Yoldi and Jimenez, using micrographic and thermal analysis methods, verified the data of these earlier workers, locating the eutectic composition close to 97.7% lead and the eutectic temperature at 300-305°C.

Fig. 1—Lead-silver constitution diagram.

diffusion and electrical conductivity studies. According to Seith and Keil, the limit of solid solubility is almost a linear curve falling from about 0.1% silver (.18 atomic per cent) at the eutectic temperature to about 0.05% silver (.09 atomic per cent) at 200°C. While not of value in determining exact solubility limits, the potential curves of Laurie¹⁰ and Puschin are of some interest.

The density of the alloys varies in a substantially linear fashion with the composition, according to the work of Matthiessen.¹¹ Spencer and John,¹² Stephens and Evans,¹³ Spencer and John as well as Stephens and Evans measured also the magnetic susceptibility of the alloy series. The effect of relatively small amounts of silver in raising the recrystallization temperature of cold worked lead was noted by Russell¹⁴ and in increasing the creep strength of lead was noted and discussed by both Russell¹⁵ and by Greenwood.¹⁶ Ludwik¹⁷ measured the hardness of several low-silver lead alloys. Fink and Pan¹⁸ demonstrated that alloys of this series were usefully resistant to anodic corrosion in brine solutions, the 61% silver alloy being recommended by them for this purpose. Tainton, Taylor, and Ehrlinger¹⁹ found that the addition of 0.5-1.0% of silver to lead anodes made possible the production of electrolytic zinc of much lower lead content than that obtained when pure lead anodes were used. Lead-silver solders containing small percentages of silver are described by Silberstein²⁰ and Johnson;²¹ the advantage of these solders is that they melt at a higher temperature than ordinary lead-tin solder.

Constitution of Lead-Tin Alloys

By W. A. Cowan* and G. O. Hiers†

This is a eutectiferous system and there are solid solutions of tin in lead and lead in tin. The results of various investigators are contradictory in respect to further constituents which may exist. Future X-ray investigations may help to establish the diagram with finality.

The Liquidus—The liquidus curve ABC in Fig. 1 indicates a system with no compound and with the eutectic at 62% tin at a temperature of 183°C.

The lead branch of this curve AB is slightly concave for approximately half of its length and convex for the remainder. The tin branch BC is slightly concave to the lower region of the diagram.

The Solidus—The line AD represents the final solidification of the lead-rich end for alloys from 0-19.5% tin. This line is drawn from Stockdale's results.

The line DBE is the eutectic horizontal occurring at 183°C. All alloys from 19.5-97.4% tin become totally solid at this temperature. The line CE represents the solidus for alloys containing 0-2.6% lead, the maximum solid solubility determined by Jeffery.

Alloys of temperature and concentration shown in the area ADB will consist of crystals of solid solution alpha and liquid.

Alloys represented in the area CEB will contain crystals of the solid solution beta and liquid.

Changes in the Solid Alloys—The dotted curve DF shows the limit of solid solubility of tin in lead. It represents a compromise of determinations of Stockdale, and Parravano and Scortecchi. This solubility changes rapidly from 100-183°C.

Fig 1—Lead-tin Constitution Diagram.

It may be noted that the solubility is 19.5% tin at 183°C., and drops to about 13% at 155°C. In alloys containing from about 18-62% tin, cooling curves in thermal studies of great sensitivity detect a slight exothermic point at approximately 155°C. In former diagrams this has been included as a horizontal line indicating a phase transformation. However, the experimental evidence may be construed as proving the change is not constitutional but merely due to supersaturation and a sudden precipitation permitted by the molecular mobility of the alloy.

Alloys in the indicated area ADF, when in equilibrium, consist entirely of solid solution alpha exhibiting a one-phase polygonal structure under the microscope. In practice, long annealings are necessary before complete equilibrium is established.

Beta is a solid solution of lead dissolved in tin and is represented by the indicated area CEG.

It may be noted that the lower limits of the solid solutions alpha and beta are not completely defined but undoubtedly will be in the future, with certainty.

Pure tin is noted for 3 allotropic forms: Gamma tin stable at 232-161°C.; beta tin stable at 161-18°C.; and alpha tin stable below 18°C. The influence of these transformations does not appear to justify the inclusion of such forms as phase change horizontals in the diagram, Fig. 1.

More thorough investigations may show such transformations in pure binary tin-lead alloys containing less than 10% lead.

X-Ray Evidence—Phebus and Blake studied lead-tin alloys by X-ray methods. They show a solid solution from 0-3.6% tin in lead, which corresponds to the face-centered cubic lattice of lead and varies in size from 4.942-4.931 Å. Alloys of 10-95% tin exhibit mixtures of the lead and tin lattice types.

*Asst. Chief Chemist, †Metallurgist, National Lead Co., New York.

This article not revised for this edition.

Alloys between 95-100% tin show the tetragonal lattice of pure tin, both in structure and size.

Physical Constants of Lead

By James E. Harris*

Atomic Weight—The atomic weight of lead is 207.22. Lead is unique among the commonly occurring elements in that specimens have been found having atomic weights differing materially from the usually accepted value. These samples have in all cases been found associated with radioactive materials and have undoubtedly been formed by the radioactive disintegration of elements of higher atomic weights. Determination of the atomic weights of samples of lead from such sources by O. Honigsmid and coworkers and by T. W. Richards and coworkers have given values ranging from 206.046¹ to that of ordinary lead. Two determinations, those of Soddy and Hyman² and of O. Honigsmid³ give values higher than that of ordinary lead; namely, 208.4 and 207.92 respectively.

Atomic Number—The atomic number of lead is 82.

Isotopes—F. W. Aston⁴ has determined the percentages of abundance of the isotopes of lead as follows: 204 (1.5), 206 (28.3), 207 (20.1), 208 (50.1). J. L. Rose and R. K. Stranathan⁵ have made similar determinations as follows: 204 (0.8), 207 (21.4), 206 (26.3), 208 (51.5).

Allotropic Modifications—Cohen and Helderman⁶, Heller⁷, Janecke⁸, and others have come to the conclusion that lead exists in two allotropic modifications with a transition point at about 50°C. This conclusion is based in part on the fact that when lead is used as a cathode in a solution of lead acetate and nitric acid there are marked structural changes, the volume increasing slightly, the color changing to gray, the metal losing its malleability and firmness. Janecke by measuring the pressure-temperature cooling and heating curves found indications of a transition point between 59–62°C. Bridgman⁹ found no evidence of allotropy in his observations of the thermo-electric properties of lead. A. Thiel¹⁰ concludes that the results obtained by Heller, Cohen and others are due to chemical changes since the disintegration takes place only in the presence of nitric acid. Rawdon¹¹ could find no evidence for the existence of lead in allotropic modifications.

Density—The density at 20°C. of lead cast in vacuo is 11.3437 ± 0.0001^{12} . The density of solid lead at the melting point is 11.0¹³. The densities of molten lead at the temperatures indicated are given in Table I¹⁴.

Table I

Temp. °C.	Density	Temp. °C.	Density	Temp. °C.	Density	Temp. °C.	Density
331	10.663	416	10.558	555	10.382	694	10.219
345	10.642	459	10.507	577	10.360	717	10.200
356	10.632	486	10.475	580	10.354	731	10.188
411	10.583	529	10.423	650	10.265

The density of molten lead at the melting point is found by extrapolation of the above data to be 10.667.

The density of lead derived from radioactive materials has been found to differ from that of ordinary lead in such a way as to make the atomic volume constant.

Compressibility—The compressibility of lead or percentage change in volume with unit change in pressure of one megabar is given by Richards and White¹⁵ at 25°C. between 100 and 500 megabars as 2.40×10^{-6} .

Crystal Form—Lead crystallizes in the face centered cubic lattice with the edge of length 4.9389 Å.¹⁶

Melting Point—The melting point of lead is $327.35^\circ\text{C.} \pm 0.05^{17}$.

Boiling Point—The boiling point of lead is variously given from 1525–1870°C. J. Johnston¹⁷ computes the boiling point from vapor pressure data at 1640 and Rodebush and Dixon¹⁸ at 1619°C. H. C. Greenwood¹⁹ and W. R. Mott²⁰ give 1525;

*Research Metallurgist, Bell Telephone Laboratories, New York.

Ruff and Bergdoll²¹, 1555; H. Von Wartenburg²², 1580 ± 20 ; P. Walden²³, 1700; and J. J. Van Laar²⁴, 1870°C. as the boiling point of lead.

H. C. Greenwood gives the boiling points at different pressures as follows:

Pressure in Atmospheres	0.14	0.35	1.0	6.3	11.7
Boiling Point °C.	1325	1410	1525	1873	2100

Critical Temperature and Pressure—J. J. Van Laar²⁴ estimates the critical temperature as 3000°C. and the critical pressure as 370 atmospheres. P. Walden²³ gives 3598 and W. Herz²⁵, 2696°C. as the critical temperature.

Heat of Fusion—Awbery and Griffiths²⁷ have found the heat of fusion of lead to be 6.26 cal. per g.

Heat of Vaporization—Rodebush and Dixon²⁷ give 223 cal. per g. for the heat of vaporization of lead.

Specific Heat

Specific heat²⁸ (mean) —180–20°C.....0.0300

Specific heat²⁸ (mean) 0–100°C.....0.03046

Naccari²⁹ gives the following values for the specific heats at the temperatures indicated:

°C.	15	50	100	150	200	250	300
Specific Heat	0.02993	0.03040	0.03108	0.03176	0.03243	0.03312	0.03380

Dixon and Rodebush³² give the following values in cal. per g. for the specific heats of liquid lead at the temperatures indicated:

°C.	365	378	418	459
Specific Heat	0.0335	0.0338	0.0335	0.0335

Thermal Conductivity of Lead—S. Konno³³ gives the following values for the thermal conductivity of lead. The values are given in cal. per cm. per sec.

°C.	0	100	200	400	500	600	700
Thermal Conductivity	0.063	0.081	0.077	0.038	0.037	0.036	0.036

Thermal Expansion of Lead

Linear coefficient of expansion³⁴ per °C. (mean) 10–100°C..... 29.5×10^{-6}

Linear coefficient of expansion³⁴ per °C. (mean) —190–19°C..... 26.5×10^{-6}

Cubical coefficient of expansion³⁴ at 20°C..... 85×10^{-6}

Electrical Resistivity and Temperature Coefficients of Resistance—Table II gives the electrical resistivities and temperature coefficients of resistance as determined by Pietenpol and Miley.³⁵ The temperature coefficients given are those defined by the equation:

$${}^{\circ}t_1 \quad t_2 = \frac{2(R_2 - R_1)}{(R_2 + R_1)(t_2 - t_1)}$$

The temperature coefficient of resistance as defined by the equation $R = R_1 + a_1(t - t_1)$ and calculated from the above data for the range 0–100°C. is 0.00406 as compared to the value of 0.00421 given by Bridgman³⁶.

For low temperatures H. K. Onnes and coworkers give the following figures, in values referred to the resistivity of lead at zero °C. as unity.

°C.	—103.61	—195.15	—216.61	—258.70
Electrical Resistivity	0.59548	0.25257	0.17129	0.01311

At the temperature of liquid helium, lead becomes a superconductor.

Table II

Temp. Range °C	a	Temp. °C	Resistivity Micro-ohms per cu. cm.
20-40	0.00336	20	20.648
40-60	0.00341	40	22.084
60-80	0.00335	60	23.645
80-100	0.00332	80	25.285
100-120	0.00311	100	27.021
120-140	0.00302	120	28.787
140-160	0.00299	140	30.582
160-180	0.00293	160	32.468
180-200	0.00291	180	34.413
200-220	0.00275	200	36.478
220-240	0.00273	220	38.542
240-260	0.00251	240	40.697
260-280	0.00246	260	42.791
280-300	0.00322	280	44.946
300-320	0.00665	300	47.938
320-330	0.0554	320	54.761
330-340	0.00116	330	96.735
340-360	0.000576	340	97.867
360-380	0.000570	360	99.000
380-400	0.000577	380	100.255
400-420	0.000561	400	101.418
420-440	0.000559	420	102.563
440-460	0.000558	440	103.716
.....	460	104.878

Temperature Coefficient of Electrical Resistivity—The temperature coefficient of electrical resistivity of lead is given by Bridgman³⁰ for the range 0-100°C. as 0.00421.

Thermal Emf. of Different Elements Against Lead—The values for the constants in the equation $\frac{dE}{dt} = A + Bt$ are given in Table I. The thermo-electric powers at 20 and 50°C. and the neutral points are also given. The values given have been compiled by F. E. Fowle⁴⁰ from data presented by Becquerel, Mathiessen and Tait.

Electrode Potential—G. N. Lewis and T. B. Brighton give the normal electrode potential of lead against the normal calomel electrode as 0.4125 volt and against the normal hydrogen electrode as 0.1295 volt.⁴¹

Surface Tension—The following values from 327-500°C. are given by T. R. Hogness⁴² and from 750-1000°C. by Drath and Sauerwald⁴³. The values given are in dynes per cm.

°C.	327	400	500	750	900	1000
Surface Tension	444	438	431	423	401	397

Capillary Constant—Drath and Sauerwald⁴³ give the value 8.37 for the capillary constant.

Viscosity—The following values for the coefficient of viscosity of molten lead are given by R. Arpi⁴⁴. The values are in cgs. units.

°C.	340	376	419	470
Viscosity	0.0189	0.0167	0.0160	0.0144

Optical Properties—H. Von Wartenberg⁴⁵ gives for the index of refraction of lead for wave length 0.589μ the value 2.01; for the absorption index 3.48; and for the reflecting power 62%.

A. K. Aster⁴⁶ gives for the index of refraction of molten lead for a wave length of approximately 0.602μ the value 0.415 and for the absorption coefficient 1.76. Both were found to be constant over the temperature range 335-485°C.

Table III
The Thermoelectric Power of Lead Against Other Metals

Substance	A Micro- volts	B Micro- volts	Thermoelectric Power at Mean Temp. of Junctions (Microvolts)		Neutral Point

Tensile Strength, Elongation, and Hardness—The following data are given by Hiers⁴⁷ for pure lead and two grades of commercial lead in the cast form.

	Southeastern Missouri Desilverized	Chemical Lead	Very Pure Lead
Yield point (0.5% elongation) (psi.).....	861	1643	714
Ultimate tensile strength (psi.).....	1966	2765	1609
Elongation (%).....	64.2	50.2	68.6
Reduction in area (%).....	92.4	87.9	100.0
Brinell hardness number 1 hr. after casting.....	4.2	5.5	2.9
Brinell hardness number 10 days after casting.....	4.1	5.4	3.0

Elastic Limit—Faust and Tammann¹⁰ have determined the elastic limit of lead by subjecting a highly polished specimen to a pull and observing microscopically the point at which the polish just begins to disappear. By this method the elastic limit of lead which had been melted and allowed to cool slowly was found to be 25 kg. per sq. cm. or 355 psi.

Young's Modulus—The values found for Young's modulus for lead vary from 1500-1900 kg. per sq. mm., 1800 per sq. mm., or 2.56×10^6 psi. may be taken as a representative value.

The Properties of Lead-Antimony Alloys

By Earle E. Schumacher† and G. O. Hiers*

General—The constitution of lead-antimony alloys is given on page 1516 of this Handbook.¹ The features of greatest technical interest in lead-rich, lead-antimony alloys are those associated with "dispersion" or age hardening phenomena. Age hardening of these and similar alloys is brought about by heating them to a temperature above the solid solubility curve¹ and then cooling them rapidly to a temperature below this curve and aging. In general, the rate and degree of hardening become greater with increase in antimony content (up to the limit of solid solubility), with increase in concentration of impurities, and with increase in the rate of cooling.² The antimony, which is precipitated in a highly dispersed state by this treatment, gradually agglomerates during continued aging, even at room temperature, and the alloys eventually soften. The rates at which agglomeration and softening take place increase with increase in aging temperature (up to the solid solubility temperature) and are greatly increased by cold work.³

Microscopic, thermal, electrical resistivity, X-ray analyses and other evidence unite in confirming the above commonly held view of the nature of the lead-antimony system. However, thermodynamic considerations suggest other views. For instance, F. H. Jeffery⁴ postulates the formation of the compound Pb_3Sb , while Chu-Phay Yap⁵ believes the evidence necessitates the presence of Sb_2 in solid solution.

Lead-antimony alloys containing from 0.5-1.0% antimony are extensively used as cable sheathing materials.⁶ In the United States, almost all telephone cables are sheathed with a lead-1% antimony alloy. Since this alloy has been so extensively used, it has naturally been carefully studied and a large amount of data collected. It is desirable, therefore, to consider some of the properties of this alloy separately.

Properties of 1% Antimony-Lead Alloy

Electrical Conductivity—The resistivity at 0°C. of supersaturated solid solutions of lead-antimony alloys containing from 0.4-1.1% antimony has been determined by Schumacher and Ferguson.⁶ Under these conditions, the resistivity of lead-1% antimony alloy is 2.415 ohms per m.g. The conductivity of various lead-antimony alloys in equilibrium at 25°C. has been determined by Schumacher and Bouton.⁷ The lead-1% antimony alloy has a conductivity of 45,350 mhos per cm.

Corrosion—The corrosion of lead-1% antimony under different conditions has been studied by Burns and Freed,⁸ and others.^{9,10} Burns and his co-workers¹⁰ developed an electrical resistance method of measuring the corrosion of lead by acid vapors and by this method found that the corrosion of lead-1% antimony in creosoted wood ducts is definitely associated with the presence of acetic acid vapor, oxygen, and carbon dioxide.

Grain Growth—The growth of grains in lead-1% antimony alloy has been studied by Dean and Hudson,¹¹ who report that crystal growth of this material proceeds with a velocity proportional at any instant to the difference between the ultimate volume and the mean crystal volume at that instant. These workers also found that the ultimate or equilibrium volume of the crystals is an exponential function of the temperature and a linear function of the amount of working as measured by the decrease in height of a cylindrical slug.

Effect of Impurities—The effect of impurities contained in a lead-1% antimony alloy on the rate and extent of its aging has been studied by Schumacher, Bouton, and Ferguson.¹² Most impurities, and especially arsenic, greatly increase the rate and extent of age hardening.

Lattice Parameter—X-ray investigations of Obinata and Schmid¹³ indicate that the lattice parameter of pure lead ($a = 4.9389\text{\AA}$) is reduced by 0.01% by the presence in solid solution of 1 atomic per cent antimony.

Mechanical Properties—Extruded cable sheath made of Grade II A.S.T.M. lead and containing 1% antimony has the following properties when cooled slowly and aged one month at room temperature:

Tensile Strength—2750-3050 psi. as measured on tensile specimens having a reduced section 3 in. long, $\frac{1}{2}$ in. wide, and $\frac{1}{4}$ in. thick and pulled at the rate of $\frac{1}{4}$ in. per in. of free length per minute.

†Metallurgist, Bell Telephone Laboratories, New York.

*Metallurgist, Research Laboratories, National Lead Co., New York.

Elongation—30-40% in 2 in. of specimen length across the break.

Rockwell Hardness—30-45 on the S.M. No. 30 scale. (This is a special soft metal scale used for comparing the hardness of various lead cable sheath alloys. The scale employs a 30 kg. load, a $\frac{1}{4}$ in. dia. ball penetrator, and a 2 in. dia. ball anvil. The major load is applied for 1 min. Readings are made from the red figures on the dial.)

Endurance Limit—800 psi. (50,000,000 cycles at 700 per min.) (Determined with specimens of the type described by J. R. Townsend¹⁴ and tested on a machine described by C. H. Greenall.¹⁵)

Aging Strength—Quenching this alloy from 250°C. produces a tensile strength of about 2,800 psi. which subsequently increases to about 6,000 psi. as a result of

Fig. 1—Solidification shrinkage and change in volume with temperature of lead-antimony alloys.

aging at room temperature. Cable sheath which cools slowly from 250°C. does not undergo this wide variation in strength.

General Discussion of Lead-Rich Alloys

Casting Properties and Thermal Coefficient of Expansion—Lead-antimony alloys containing from 7-12% antimony have good casting properties and comparatively high strength. For use as automobile storage battery grids, however, which have a lattice structure of fine ribs, it is customary to add about 0.25% tin to improve the casting quality. Die castings are often made of 10% antimony-lead. Goodrich¹⁶ determined the solidification shrinkage and volume changes of several lead-antimony alloys ranging from 0-25% in antimony content. These data are plotted in Fig. 1. The expansivity coefficient of cast lead-antimony alloys containing from 0-15% antimony as given by Vinal¹⁷ is shown in Table I. For extruded lead, Hiers¹⁸ found the coefficient of linear expansion in the range 25-185°C. to be 0.000029 per °C., and for extruded 6% antimony-lead, he found 0.000027 per °C.

Electrical Conductivity—The conductivities of various extruded lead-antimony alloy wires are given by Dean, Zickrick, and Nix¹⁹ for different aging treatments. Fig. 2 contains curves, plotted from their data, showing the conductivities of these wires, in terms of pure lead, as heat treated at 235°C. and quenched, and as heat treated, quenched, and aged at room temperature for 125 days.

The resistivities at 20°C. of lead-antimony alloys containing from 0-16% antimony given by Vinal¹⁷ are reproduced in Table I. Data on the resistivity of alloys containing up to 70% antimony published by Matthiessen²⁰ are given in Table II as they appear in the International Critical Tables.²¹

Thermal Conductivity—Data given in the International Critical Tables²⁷ on the thermal conductivity of lead-antimony alloys are plotted in Fig. 3.

Density—The density of various lead-antimony alloys as determined by Goebel²⁸ from cast specimens are shown plotted in Fig. 4. Vinal's²⁹ data on density are given in Table I.

Fig. 2—Conductivity of extruded lead-antimony wires at 20°C.

Specific Heat—The results of tests by Durrer³⁰ and by Linnavuori³¹ show that, at any constant temperature, within the temperature range of 20-100°C. the specific heat of lead-antimony alloys is a linear function of composition. (Average values of specific heat, in cal. per g. of antimony and lead within the temperature range 20-100°C. are: Lead = 0.0305; Antimony = 0.0508.)

Thermoelectric Power—According to Pelabon³², alloys having a eutectic structure usually have a higher thermoelectric power than that given by the mixtures rule. For lead-antimony, the actual values of emf. against platinum at 100°C. are given in Table V along with values calculated from the mixtures rule. Rudolf³³ also gives data on the thermoelectric power of lead-antimony alloys.

Mechanical Properties—Values of tensile strength, elongation, and Brinell hardness of commercial 4%, 6%, and 8% antimony-lead rolled sheet as reported by Hiers^{34, 35} are listed in Table III. This table gives values for the sheet as aged for various periods at room temperature after rolling, and as aged at room temperature after being quenched from a temperature of 235°C. The alloys tested were small samples cut from sheets rolled to a thickness of $\frac{1}{8}$ in. from a cast slab about 3 in. thick. Tensile strength, elongation, and hardness data given by Vinal³⁶ for cast lead-antimony alloys are shown in Table I. Both Hiers' and Vinal's tensile strength data are plotted in Fig. 5.

Brinell hardness data given by Goebel³⁷ for a series of alloys are shown in Table I (a).

Table I (b) contains data on tensile strength, elongation, and Brinell hardness for a series of alloys extruded as $\frac{1}{4}$ in. dia. rod and aged approximately two weeks at room temperature. The tensile specimens were 14 in. long with a reduced section 8 in. long by $\frac{1}{4}$ in. in dia. and were pulled at the (gross) rate of $\frac{1}{4}$ in. per min. Elongation was measured in two in. of original specimen length including the break. The Brinell tests were made with a 300 kg. load applied to a 10 mm. ball for 30 seconds.

The tensile strength of a series of lead-antimony alloys in the form of extruded wires given various heat and aging treatments has been published by Dean, Zickrick, and Nix.³⁸ Some of these data representative of a more or less standard condition of the alloy are shown in Fig. 6.

The fiber stresses which can be withstood for indefinitely long periods at various temperatures by extruded pipe composed of "chemical" lead and of 6% antimony-

Fig. 3—Thermal conductivity of lead-antimony alloys.

lead alloy have been published by the Lead Industries Association²⁸ and are reproduced in Table IV.

Welding and Soldering—Lead-antimony alloys can be welded by gas torches and other suitable heating appliances and they can be soldered by many alloys such as the lead-tin or lead-tin-cadmium eutectics. For material used in corrosive atmos-

Fig. 4—Density of lead-antimony alloys at 18°C. ± 2°C.

pheres, it is advisable that the alloy used for making the joint be of approximately the same chemical composition as the parts joined.

Bearing Alloys—Antimonial lead was one of the early lead-base bearing alloys used with satisfactory results. An alloy containing 10-12% antimony is commonly known as Standard No. 4 Babbitt metal. This alloy has excellent casting properties and can be used satisfactorily for bearings in slow moving machinery. The A.S.T.M. Standards, B23-26, lists two lead-antimony alloys and their properties as follows:

No.	Sb	Composition, %			Ultimate Strength in Compression, Pst.		Brinell Hardness No.		Pouring Temp., °F.
		Pb	Cu	As	68°F.	212°F.	68°F.	292°F.	
11	15	85	0.50 max.	0.20	12,800	5,100	15.0	7.0	630
12	10	90	0.50 max.	0.20	12,900	5,100	14.5	6.5	625

Fig. 5—Tensile strength of lead-antimony alloys.

Fig. 6—Tensile strength of extruded lead-antimony wires.

Corrosion Resistance—Lead-antimony castings containing up to 12% antimony have sufficient corrosion resistance combined with their mechanical strength to find considerable use in the chemical industry in machinery and apparatus. In some instances, particularly where chemical solutions would tend to deposit copper on lead by galvanic action, serious corrosion and pitting can be avoided to a considerable extent by the substitution of lead-antimony alloys for lead. This beneficial effect of antimony in lead is probably due to its position in the electrochemical series.

Microscopic Examination—Methods of preparing lead-antimony and other lead-rich alloys for microscopic examination have been described by Lucas¹⁴, Schumacher and Bouton¹⁷, Bassett and Snyder¹⁸, Vilella¹⁹, and others. A rapid, efficient, and frequently used method consists of simple microtoming followed by an etch with a solution of 1 part of 30% hydrogen peroxide to 3 parts of glacial acetic acid.

Properties of Lead-Calcium Alloys

By Earle E. Schumacher* and G. M. Bouton*

General—The constitutional diagram for the lead-calcium system is given on page 1520 of this Handbook. The alloys of greatest interest are those containing between 0.01% and 0.1% of calcium. Because they are age hardening, the properties may be markedly affected by the methods used in the preparation of specimens for test. Also, as is true with most other lead-rich alloys, the values obtained on tests may be strongly influenced by the manner in which the tests are conducted.

Effect of Heat Treatment on Hardness—The usual precipitation hardening procedures are applicable to lead-calcium alloys. Precipitated calcium goes into solution in a few minutes at temperatures above the solid solubility curve. Once in solution, either as a result of heat treatment or cooling from the molten state, the calcium does not precipitate rapidly from unworked alloys containing about 0.03-0.04% of calcium until the temperature falls to below approximately 200°C. This makes it possible to extrude these alloys below the solid solubility temperatures without sacrifice in hardening possibilities. It is possible to control the hardening potentialities of the alloys by precasting them, allowing them to age at room temperature for a short while to permit precipitation to start, and then, heating to and extruding at some temperature below the solubility curve. The strength attainable on aging materials produced in this latter manner is a function of the extrusion temperature.

The rate of cooling the lead-calcium alloys, after the solution heat treatment, is critical with respect to the rate at which hardening occurs during subsequent aging at room temperature, but is not critical with respect to the maximum hardness eventually attained even though the time to cool varies from a fraction of a second to several hours.

The age hardening characteristics of the alloys are interesting. Aging quenched specimens at room temperature results in a rapid initial rate of hardening followed by a slow but continued increase of hardness for a few years. Aging at 100°C. immediately after cooling to room temperature does not produce as great hardness as room temperature aging. If, however, the quenched alloys are allowed to age at room temperature for a period of time varying from a few days for the 0.1% calcium alloy to a few months for a 0.03% calcium alloy, heating for about a day at 100°C. produces an increase in hardness (or strength) to the maximum obtainable for the particular material. At temperatures between 75°C. and the solid solubility line the alloys over age. The degree of over aging depends upon the duration of the heat treatment and the temperature. This serves as one method of controlling the strength and stabilizing the alloy.

Tensile Properties—Curve 1 in Fig. 1 shows the maximum tensile strengths attainable in lead-calcium alloys by room temperature aging following solution heat treatment and quenching. Curve 2 shows the strengths determined immediately after quenching. Curve 3 shows the strengths of alloys cast in a hot mold, air cooled, and then aged 7 days at room temperature plus 16 hrs. at 100°C. This illustrates that rapid quenching is not essential and that the secondary 100°C. aging is effective in developing maximum strength in lead-calcium alloys. It is, of course, possible to stabilize tensile strength at values between those for the quenched, and those of the quenched and aged material by control of the manufacturing conditions, and by appropriate heat treatment.

Creep Properties—All investigators have reported that the lead-calcium alloys have high creep resistance. The results of tests conducted by Moore, Betty, and Dollins² on samples cut from flattened cable sheath are given in Fig. 2 and 3. While the absolute values of creep are greatly influenced by the exact history and

Fig. 1—Tensile strength of lead-calcium alloys.

*Metallurgists, Bell Telephone Laboratories, New York.

purity of the materials, these results are typical, and illustrate the degree of superiority of lead-calcium alloys over other lead-rich alloys.

Fatigue Properties—The endurance limits of lead and lead-rich alloys are given in Table I. The wide diversity of test methods and preparation procedures used by the various investigators precludes direct comparisons. However, each set of data shows lead-calcium alloys to be decidedly superior to pure lead, and it is worthy of note that no investigator has reported a lead-rich alloy having a higher endurance limit than can be obtained with lead-calcium alloys.

Fig. 2—Comparative creep of lead-calcium cable sheath materials at room temperature.

Fig. 3—Failure of lead-calcium alloys under steady load.

Table I
Fatigue Data

Investigators	Material	Endurance limit at 5×10^7 cycles, psi	Preparation of Sample and Method of Test
H. F. Moore et al. ^{1,2}	Pb Pb-0.04% Ca Pb-1% Sb	400 1,000 1,000	Samples cut from flattened cable sheath and tested as cantilever beams.
R. S. Dean & J. E. Ryjord ³	Pb-0.04% Ca Pb-0.04% Ca	1,200 1,500	
E. E. Schumacher ¹ & G. M. Bouton	Pb Pb-1% Sb Pb-0.04% Ca Pb-0.06% Ca	< 250 500 820-1,020 1,120	
J. R. Townsend ³ & C. H. Greenall	Pb Pb-1% Sb Pb-0.038% Ca	215 300-450 685-840	
		Endurance limit at 10^7 cycles, psi.	
H. Waterhouse ⁴	Pb Pb-0.026% Ca Pb-0.041% Ca	470 1,038 1,180	Samples machined from 1 in. dia. round rod extruded from 1 1/2 in. dia. slugs. Tested in tension and compression along axes of specimens.

Chemical Analysis—The accurate determination of such small quantities of calcium as are used in these alloys requires a special technique. A rapid, high-precision method⁵ is available.

Uses and Special Properties—The alloys containing 0.025-0.04% calcium possess properties which make them attractive for use as telephone and power cable sheathing. For these applications, extensive, but as yet incomplete, appraisal studies have been conducted over some years. Alloys containing 0.045-0.1% calcium possess properties which make them of interest for storage battery applications.^{6,7} Anodically and cathodically, the behavior of lead-calcium alloys containing up to 0.1% calcium is similar to that of pure lead. The rate of sulphation of storage battery elements

made of lead-0.1% calcium alloy is about one-tenth that of elements made from the present standard lead-9% antimony alloy.

Properties of Lead-Tin Alloys

By George O. Hiers*

Lead-tin alloys are used in large quantities because, among other reasons, of the ease in melting and applying to other metals in the forms of solders or coatings. Since all of the alloys throughout the entire system are readily workable, they can be rolled, extruded, swaged, and stamped, even in the cold state. The corrosion resistance of the alloys is noteworthy and important, particularly when they are used as foil and coatings such as terne and tin plate. The principal uses of the alloys may be classified approximately as follows:

% Tin,
Balance Lead

-
- | | |
|-------------|--|
| 1-3..... | Lead foil; for electrical condensers, electrical fuses, wrapping tea, bottle caps, for covering stems of cut flowers. Cable sheathing; for coverings of electrical telephone, telegraph, and power cables. |
| 3-8..... | Hot dip coatings on sheet iron or on sheet copper for roofing. Solders of the highest melting range in the system Pb-Sn. Rolled sheet and extruded pipe for tank linings, anodes, and heat transfer coils in chromium plating tanks. |
| 15-25..... | Coating sheet iron by hot dipping (terne plate). Tobacco foil. Low grade solders. |
| 25-60..... | Solders. |
| 85-100..... | Coating various metals by hot dipping. Final products; sheet "tin" or tinned iron or tin plate, "tin" cans tin lined or coated copper utensils. Tin foil. Collapsible tubes. In the U.S.A. only pure tin coatings or metal are permitted for use in contact with foodstuffs. |
-

Density—Goebel¹ determined the density values for the solid alloys (Fig. 1), while Goodrich² obtained values for the liquid metal. Goodrich also determined solidification shrinkages. These data are given in Fig. 2 and 3. A change in state of beta to alpha allotropic forms occurs with pure tin at and below 18°C. "Tin disease" is a disintegration of the metal due to the density change of 7.29-5.85 accompanying the allotropic change. It is practically unknown in the Pb-Sn alloy system where lead is present in amounts of over 10%. Tammann describes lead as an inhibitor of "tin disease." The allotropic change from gamma to beta tin at 161°C. is also accompanied by a volume change shown in Fig. 3.

Tensile Properties—Values for tensile strength and elongation of the cast alloys, as determined by several investigators, are shown in Fig. 4. Other strength characteristics at elevated temperature are shown in Fig. 5 and 6, as given by Hiers.³ It has been realized that the values obtained in a testing machine operated at a normal rate, say a movement corresponding to ¼ in. per min. of free crosshead travel relative to 1 in. of test length of specimen, are markedly higher than those obtained at slow rates in a testing machine or in actual service. At 25°C., the cast alloys are generally stronger than those in the rolled or extruded states. Various studies⁴ of the mechanical properties of the eutectic alloy in fabricated states have been made in England in the last few years.

Hardness—Brinell hardness values for chill castings, as determined by Goebel¹ are shown in Fig. 7. He used a 4 mm. ball with load of 20 kg. applied for 20 sec.

Creep Data—For a 2% tin alloy in the extruded form, Moore⁵ gives 650 psi. as the stress for fracture under steady tensile load for one year. For the same metal, he estimated 4% creep (or elongation) in 10 years at:

275 psi. tensile load at 0°C.
170 psi. tensile load at 25°C.
105 psi. tensile load at 65.5°C.

Tests have been made of the strengths under continuous load of soldered lap seams used for copper roofing in an investigation conducted at the Bureau of Standards.⁶ As a result of these tests, it was decided that the seams should be at least ¼ in. wide, and the maximum safe load for these seams was placed at approximately 350 psi. (length times width) of seam. For ½ in. pretinned flat lock seams 375 psi. of seam area was the maximum safe load. The values apply to the use of a 50% tin solder.

Fatigue Resistance—Moore⁵ has determined 800 psi. as an endurance limit for 2% tin extruded alloy when tested for 50,000,000 cycles of stress at 2,500 r.p.m.

*Metallurgist, National Lead Co., New York.
This article not revised for this edition.

Fig. 7—Brinell hardness for chill castings at 20°C.

Fig. 8—Electrical resistivity and thermal conductivity.

Fig. 9—Coefficient of linear expansion.

Under the same test conditions, he has found commercial lead to have an endurance limit of 400 psi.

Thermal and Electrical Data—Graphs representing data given in the International Critical Tables^{7, 8} are shown in Fig. 8 for Thermal and Electrical Conductivities. Linear expansion⁹ data are given in Fig. 9.

Notes Regarding Solder—While the solder alloys are discussed more fully on page 1205 it may be repeated here that when soldered joints are depended upon for considerable strength, it is well, when possible, to use re-enforcements, such as crimped, lapped, or interlocking seams, rivets, cleats, or bolts, before soldering. Thus the solder may be relieved of the load and its major function becomes that of hermetically sealing the joints.

The Properties of Lead-Tin-Antimony Alloys

By George O. Hiers*

Constitution—These alloys are important, particularly in use as bearing metals, casting metals, and type metals. There is a ternary eutectic at 462°F. (239°C.) with the composition 84% lead, 4% tin, and 12% antimony. At 477°F. (247°C.) there is a pseudo-binary eutectic point with the composition 80% lead, 10% tin and 10% antimony.¹ This appears to be a eutectic between lead and the compound SbSn.

General Casting Properties—The usual type metals and bearing metals do not greatly differ in composition from the eutectic and the pseudo-eutectic alloys mentioned. They were developed in such regions largely because of fusibility and ease in casting. Contrary to statements in the old literature type metals do not expand on solidification, but actually shrink about 2% in volume while solidifying. Alloys containing more than 12% antimony are preferably chill cast in order to prevent segregation. In the higher antimony alloys cubic crystals of antimony or of beta solid solution (SbSn) tend to float upward in the otherwise liquid metal due to the higher melting point and lower density of the cubes.

Type Metals

	Tin, %	Antimony, %	Liquidus, °F.	Brinell Hardness No.
Electrotype	3	3	570	14
Line type {intertype {linotype }	4	11½	475	22
{Ludlow }				
Stereotype	5	14	493	23
Government alloy	6	12	491	23
Monotype	7	16½	527	26
Foundry type	14	24	605	32

Type Metal—Foundry type metal, linotype, intertype, Ludlow, and monotype are cast automatically in machines operated like typewriters. Newspaper stereotype metal is cast in curved plates, reproducing a replica from a paper or composition matrix. Flat stereotype plates are used for books and other commercial work. Electroplated coatings of nickel, copper, or chromium have been used to prolong the life of the printing face of type metal. The metal recently used in the United States Government printing office is a compromise alloy used in all type casting machines and for making stereotypes.

Electrotype alloy is used for backing thin sheet copper replicas (electrotypes) of type or illustrations. It is cast adherently upon the reverse side of the thin electroplates with the aid of solder foil and flux.

Grid Metal—Alloys containing 6-12% antimony balance lead are markedly improved in casting qualities with the addition of ¼-½% tin. It is for this reason the grid metal in automobile storage batteries (of the starting type) has such composition.

Mechanical Properties—Tin strengthens lead appreciably, but antimony does so to a greater extent when added in similar amount. Ellis² studied the tensile strength, compressive strength, and hardness of 21 of the lead-rich ternary alloys containing up to 30% each of tin and antimony. His results are given in Table I. Weaver¹ studied the Brinell hardness of a similar series of alloys with results given in Fig. 1. Test data from the National Bureau of Standards³ are presented in Table III.

Thermal and Physical Properties—Table III gives the density of the alloys and also melting characteristics. Table II shows data pertaining to heat energy required for melting.⁴

Age Hardening—Solid solubilities of tin and antimony have been determined for the lead-rich corner of the ternary system.⁴ According to Weaver, 2½% each of antimony and tin are soluble together in lead at the eutectic temperature, 477°F. While the rolled and extruded alloys are markedly susceptible to heat treatment and age hardening, particularly in the alloys containing a few percent each of tin and antimony, it so happens that the ternary alloys are used almost exclusively in the cast state. Generally, in the cast state the age hardening of the commercial alloys appears of no consequence. However, storage battery grid metal usually becomes slightly harder and slightly brittle on aging. This appears due to

Lead-Base Bearing Alloys

By Leland E. Grant*

General—Alloys of lead have been used as bearing metals for a long time with excellent results. In general these alloys are not quite so satisfactory as are the tin-base alloys under severe service conditions, but their low cost and all around good properties make them desirable in numerous applications. They are especially suitable where they are not subjected to extreme high speeds, heavy loads, or severe impact. When the size of the bearing can be increased they can often replace tin-base metals. A large tonnage is consumed annually by the railroads for freight and passenger car bearings. The alloys are also used for electric motors and machinery bearings. Packing for piston rods and pump shafts are another type of bearing in which they are used.

Two basic types of lead-base bearing alloys are in use at the present time. The older type consists of lead hardened with antimony and tin, with additions of copper or arsenic in special cases. The new type is an alloy containing approximately 98% lead, the remainder being calcium and small amounts of other metals. This type has not yet come into extensive use in America but has been used on the German State R. R. for a number of years.

Specifications—A specification for lead-base bearing alloys has been prepared by the A.S.T.M. Table I was selected from the various alloys included in this specification. The S.A.E. has two specifications, Nos. 13 and 14, for lead-base bearing alloys which are the same as A.S.T.M. alloys 9 and 7 respectively. Table II shows the composition of the journal bearing lining alloy in the A.A.R. specification M-501-34.

It will be noted that the above specifications all call for approximately 65% or more lead. Only in a few alloys used for packing does the lead fall below 65%.

Effect of Antimony—The range of antimony content is quite restricted; it seldom exceeds a maximum of 15% and is generally close to 10% when a minimum amount is needed. Antimony combines with tin to form cubes of the solid solution SbSn in some compositions. When these cubes become so numerous that they are nearly continuous throughout the structure the alloy becomes hard and relatively brittle under impact. This condition is avoided if the antimony does not exceed 15%. Small amounts of the cubes are desirable in heavy duty alloys for the hardness and strength they impart. Antimony also forms a pseudo-eutectic with lead and this constituent is the source of a large part of the strength the alloys possess. Antimonial lead was one of the early lead-base bearing alloys used with satisfactory results. These binary alloys are still used to some extent but the great improvement in properties produced by the addition of 2-5% tin more than compensates for the small increase in cost.

Effect of Tin—The permissible range of tin in these alloys is great. In the softer alloys it may be eliminated entirely as explained above, but a much more serviceable alloy is obtained if about 5% tin is present. The maximum for tin is about 20%. Unlike antimony, it does not cause brittleness in relatively large amounts, but beyond 20% tin no marked improvement in properties for good bearing purposes is obtained. Tin enters into solid solution in both lead and antimony and is present in the compound that forms the major portion of the SbSn cubes. It is in these forms that tin participates in the pseudo-eutectics and other constituents which contribute to the hardness and strength.

Effect of Copper—Segregation may become a problem when the tin and antimony are high owing to the tendency of the specifically lighter cubes to float to the top. This can be overcome by the addition of 1-2% copper. The mechanism by which copper prevents segregation has not been fully explained. Sometimes the copper unites with antimony to form long purple needles of the compound Cu_3Sb . These entangle the cubes and prevent them from rising. However, this is not always the case although the evidence does indicate that some reaction takes place in the molten alloy due to the presence of the copper. Frequently a web-like structure is to be seen in the cubic crystals and it is possible this is a result of the addition of copper. Copper should not be used in the alloys of low tin content as it is likely to cause

*Chief Chemist, Chicago, Milwaukee, St. Paul & Pacific R. R. Co., Milwaukee.

This article was not revised for this edition.

frothing when the alloy is poured, unless the pouring temperature is raised considerably. It is for this reason that copper is limited to 0.5% max. in most of the alloys.

Effect of Arsenic—Arsenic also is effective in preventing segregation. It produces a profound change in microstructure, causing a disappearance of the cubes in those alloys where cubes would normally be formed and refining the entire grain structure very markedly. It appears to prevent segregation through a reaction with the normal constituents of the alloys, the effect becoming more pronounced with increasing arsenic. In addition to preventing segregation it raises the hardness at both normal and elevated temperatures. There has been a limited amount of arsenical lead-base bearing alloys marketed in which up to 2.5% arsenic is incorporated. Generally it is substituted for a large part of the tin. Such alloys have not been used extensively probably because they are relatively brittle when the arsenic exceeds 1%. Where brittleness is not serious but where segregation is to be prevented in large bearings such as those for rolling mills, this alloy is used.

Impurities—Little information is available on the effect of impurities on the properties of the lead-base bearing alloys. There is no indication that the small amounts of foreign metals associated with lead and tin are harmful. On the contrary they appear to be beneficial since they act as hardeners in the commercially pure alloys and thus contribute somewhat to the final hardness and strength exhibited by the bearing alloys. Arsenic is normally the principal impurity and its effect has been discussed. Zinc acts in a manner similar to arsenic, increasing the hardness and preventing segregation, but the method by which it prevents segregation is unknown.

Brinell Hardness—The Brinell hardness of the lead-base bearing alloys naturally varies with the composition. Most of the alloys used commercially have a Brinell number between 18 and 23 at 70°F. (10 mm. ball and 500 kg. load). Those that do not contain tin will have a Brinell hardness of around 15. Increase in temperature causes rapid softening so that at 212°F. the hardness is approximately one half of the value at 70°F.

Compression Strength—The ultimate strength in compression of these alloys not containing tin normally lies between 14,000 and 16,000 psi. at 70°F. and decreases more rapidly in proportion than does hardness with increase in temperature. It is apparent from this that overheating of this type of bearing alloy is likely to result in excessive squashing of the lining. The hardness and strength of the lead alloys are significantly lower than the similar values for the tin-base bearing alloys.

Casting Properties—Lead-base alloys have low pouring temperatures (617-653°F.) and excellent casting properties. The metal retains its fluidity down almost to the freezing point (about 465°F. for a majority of the alloys). These properties are a distinct advantage as the casting operations are simplified thereby and at the same time loss of metal by drossing in the melting pot is reduced.

Pouring temperature and rate of cooling exert a profound influence on the microstructure and physical properties of this class of alloys. Too rapid cooling leads to the formation of a structure too fine for the production of the best bearing alloys. Too slow cooling, high pouring temperature, and a mandrel or back that is too hot, promote segregation and formation of a coarse structure with a tendency to brittleness, low compressive strength, and low hardness. The compressive strength and hardness increase with the pouring temperature to maximum values at about the recommended pouring temperatures and then decrease. It is the effect of this variation in cooling rates that undoubtedly accounts for differences in the physical properties that are found in the literature for alloys of essentially the same composition.

Lead-Calcium Bearing Alloys—There are two commercially important bearing alloys containing 97% lead. These are Bahnmetall and Satco. A typical composition of Bahnmetall is as follows:

Lead 98.63, calcium 0.69, sodium 0.62, lithium 0.04, aluminum 0.02%.

The Satco alloy contains tin, magnesium and calcium as the principal hardening elements. Bahnmetall has a Brinell number of 25-35 at 70°F. and Satco about 20. The hardness does not fall off with increase in temperature as rapidly as in other lead-base bearing alloys. These alloys also have higher compressive strengths which fall but slowly when the temperature is raised. Bahnmetall has a compressive strength of 25-30,000 psi.

Bahnmetall has a number of valuable properties but lacks some of the good characteristics of the ordinary lead-base alloys. Its pouring temperature (878-

1112°F.), coefficient of expansion, rate of wear, and shrinkage are all high. The alloy drosses heavily and thereby loses its hardening elements so rapidly that it cannot be remelted and used a second time. Adhesion to solder is poor and mechanical anchorage must be relied upon to hold the lining. Admixture with ordinary lead-tin-antimony alloys causes the hardening elements of Bahnmittel to separate. The metal will carry heavy loads and stand considerable abuse without damage. This is partly due to its relatively high hardness and good plasticity. Temperatures that would cause other lead-base bearings to run out do not harm Bahnmittel. Liners of this alloy can be cast accurately to size and applied without broaching, an item of considerable economic significance in the case of railroad car bearings. But under heavy loads and fairly high speeds the alloy has a tendency to develop hair line cracks which ultimately cause failure.

Satco does not lose its hardening constituents readily when melted but it does form a large volume of dross compared with lead-base babbitts. This is due in part to the high pouring temperature required (932-1004°F.). The alloy solders readily with any of the common solders and makes a strong bond. It can be handled in the same equipment as is used for ordinary babbitts but due allowance must be made for the high pouring temperature. It should not be contaminated with ordinary lead-base bearing metals. It stands pounding well, has about the same wear rate as other lead-base babbitts, and is not damaged by local overheating that would be likely to ruin an ordinary lead-base alloy. Satco is being used to some extent in automotive, railroad, marine, and general industrial service, but its ultimate sphere in the bearing field cannot yet be determined.

Preparation of Lead and Lead Alloys for Metallographic Examination

By J. R. Vilella*

Polishing—Because of the softness of lead and its alloys, the preparation of specimens for microscopic examination has always been a difficult task. Two main difficulties are encountered:

1. The finished surface is usually too heavily scratched.
2. The surface metal flows, forming a layer of cold worked metal that masks the true structure.

The usual way of overcoming these difficulties has been to etch deeply so as to get below the surface imperfections. However, a deep chemical attack roughens, blackens and obliterates the fine details of the structure. It is therefore desirable to be able to finish the samples with a minimum of scratches and flowed metal so as to permit light etching.

Two basic methods and several modifications thereof intended to overcome these difficulties have been described.^{1,2} One of these is based on the use of a robust rigid microtome, equipped with a specially sharpened knife capable of producing a smoothly cut surface suitable for etching and microscopic examination without further polishing. The other method requires no special equipment. It is based on the fact that scratches and flowed metal can be eliminated by a series of alternate light polishings and etchings.

Microtome Method—The success of this method depends on three factors:

1. The microtome must be sufficiently rigid for the service.
2. The knife must be properly sharpened.
3. The instrument must be capable of cutting slices 2 microns in thickness.

1. Lucas, who originated the method, employs a Jung microtome, type K, originally designed for wood sectioning, but he states that given a solid, substantial instrument, good results are largely a matter of personal skill in sharpening the knife and manipulating the apparatus. Schumacher and Bounton³ have successfully employed an inexpensive biological microtome. They have also obtained fair results by means of a wood chisel and a special clamp.

With the Jung microtome specimens of lead, tin, platinum, gold, and silver have been successfully sectioned. Harder metals such as aluminum, aluminum alloys, copper, zinc, and the brasses and bronzes may be roughly prepared by sectioning, and then given a final polish on magnesium oxide, thus considerably expediting the usual procedure of preparation.

2. A properly sharpened, honed and stropped knife is indispensable for the success of this method. A dull or serrated edge will yield surfaces covered with scratches and cold worked metal. An edge such as is usually associated with razors is also unsatisfactory because it chips and turns over easily. Best results are obtained when the knife is sharpened to a fine chisel edge and free from all but the finest imperfections. Once a good edge is obtained, if used judiciously, it will cut 50 or more lead specimens between stroppings. Sharpening the knife is a laborious operation requiring considerable skill. Detailed instructions are usually supplied by the manufacturers.

3. Lucas finds that unless the instrument cuts sections as thin as 2 microns the cut surface is not suitable for etching. The shavings themselves are not used for metallographic study, but if they are thicker than 2 microns it will be found that the cut surface of the specimen will contain cold worked metal and scratches. This is an indication that the knife has not been properly honed or stropped. It should be noted that even well cut and etched specimens present to the unaided eye the appearance of slight furrows or undulations on the prepared surface. These imperfections are not troublesome under the microscope.

Wood Chisel Method—This method gives satisfactory results when properly used. The specimen is mounted in a hardened tool steel clamp and the excess material

*Metallurgist, United States Steel Corp., New York.

¹For the references, see the article "Etching Lead and Lead Alloys for Metallographic Examination," which follows this article.

²This article not revised for this edition.

removed with a coarse hacksaw. A rough chisel cut is made, followed by a fine one using the surface of the clamp as a guide.

Polishing with Standard Equipment—This method is rapid and can be successfully carried out with ordinary polishing equipment, or by hand, and when properly executed leads to the formation of ideal surfaces for microscopic examination at both low and high magnifications.

Procedure—(1) To minimize distortion of the surface metal, the sample should be cut with a sharp hacksaw, taking care to avoid dragging and pushing. It is well to smear the saw blade with a few drops of oil.

(2) The specimen should then be ground with gentle pressure on a coarse emery paper that has been previously smeared with a concentrated solution of paraffin in kerosene. This prevents the particles of lead from adhering to the paper and forming a glaze which drags and distorts the surface metal. At least $\frac{1}{4}$ inch of metal should be ground away during this step. The speed of the revolving disks should not exceed 500 r.p.m. at any stage during the entire operation.

(3) The specimen is then ground successively on No. 2, No. 1, No. 0, No. 00, and No. 000 emery papers, all previously smeared with the solution of paraffin in kerosene. Grinding on successive papers should be continued for at least one minute after all the scratches left by the preceding one have disappeared, and care should be taken to exert the minimum pressure needed to secure good cutting action. The scratches left by No. 000 paper are frequently too deep to be easily removed during the next step (wet polishing), and for this reason the specimen should be ground, when necessary, on an old No. 000 paper that has been well worn by previous use. This last paper as a rule yields very fine, even scratches, which disappear easily during wet polishing. The specimen should now be free of all paraffin and grit.

(4) Wet polishing is carried out on a perfectly clean broadcloth smeared with an abundant supply of soap. The abrasive to be used is a water suspension of the finest levigated alumina obtainable. At this stage of the operation a black smudge often appears on the surface of the specimen. When this happens, polishing should proceed very gently, taking care to keep the cloth thoroughly wet with alumina and soap until all traces of smudge have disappeared and the surface appears bright.

(5) The scratches left after polishing on broadcloth are often rather deep and remain visible after etching. They can be removed by finishing the operation by hand on a clean pad of silk velvet well soaked with soap and alumina. The sample is then washed carefully to remove all traces of soap.

Etching Lead and Lead Alloys for Metallographic Examination

By J. R. Vilella*

According to the proponents of the sectioning methods of preparing lead specimens, it is feasible to etch the sample as it comes from the microtome. One etching is sufficient to disclose the true structure of the metal. Occasionally a preliminary swabbing with cotton well soaked in the etching reagent is employed to eliminate the heavier knife marks usually present in specimens prepared by the microtome or chisel methods.

The etching of specimens prepared by conventional polishing methods is not considered a process completely independent of polishing. Even well prepared surfaces are seldom completely free from a film of cold worked metal which must be eliminated in order to show the true structure of the specimen. This is not always satisfactorily accomplished by the etching reagent alone, no matter how long the specimen is exposed to its action. A prolonged etching attack usually results in pitting, roughening and obliterating the fine details of the structure. It is advantageous to employ a method of alternate polishing and etching by means of which the film of distorted metal is gradually removed by the reagent, while the succeeding light polishings prevent the evils of a long continued chemical attack. This process may be carried out as follows:

The polished specimen is etched in a suitable reagent and its structure noted under the microscope. It is then repolished gently on the velvet pad until bright, and reetched and examined again. A considerable improvement in the appearance of the structure will be noted. It should be again repolished and reetched, and this process continued as long as the appearance of the structure improves. As a rule, three repolishings suffice, but occasionally more may be required.

The etching reagents for lead and lead alloys are given in Table I.

Table I
Etching Reagents for Lead and Lead Alloys

No.	Authority	Composition	Remarks
1	Rutherford ⁴	3 parts glacial acetic acid 1 part 9% hydrogen peroxide	Etch for 10-30 min., depending on depth of flowed metal on the surface. Dry with alcohol and clean with concentrated nitric acid. The nitric acid is removed by sudden immersion in a large volume of water.
1a	Lucas ^{1,2}	3 parts glacial acetic acid 1 part 30% hydrogen peroxide	Etching time varies from 6-15 min. Used for lead, lead-tin, lead-antimony, and lead-calcium alloys.
2	Vilella ³	1 part glacial acetic acid 1 part nitric acid 4 parts glycerol	Etching from 10-15 sec. Best results obtained when used in conjunction with method of alternate polishing and etching. For lead, lead-antimony, lead-calcium, and low tin alloys. Use freshly prepared solution and discard after using.
2a	Bassett and Snyder ⁵	3 parts glacial acetic acid 4 parts nitric acid 16 parts water	Used at a temperature of 40-43°C. Recommended for pure lead and lead-tin alloys up to 3% tin. Etching time depends on depth of distorted metal on prepared surface.
3	Johnston ⁶	Concentrated nitric acid	Plunge specimen in concentrated acid. Wash in a rapid stream of water. Repeat operation as often as necessary. If acid becomes diluted by water carried by specimen it must be rejected and fresh acid used.
4	Bassett and Snyder ⁵	60% solution of perchloric acid	For electrolytic etching. No. 6 dry cell used to supply energy. Also recommended by Dean, Ziekrick and Nix. ⁷

Properties of Lithium and Its Alloys

By Dr. Hans Osborg*

Introduction—Lithium resembles sodium, potassium, caesium, magnesium, calcium, strontium, and barium. However, the diversity in reactivity of lithium is greater than these other elements. Furthermore, the solid solubility of lithium in certain metals is somewhat greater than that of other alkali and alkali earth metals. These two characteristics make lithium useful as a refining agent and as an alloying constituent.

Lithium as a Refining Agent—Lithium melts at 366.8°F., its boiling point is approximately 2435°F. The vapor pressure of molten lithium is relatively low. At 1700°F., it is only 17 mm. Hg, and at 1775°F. it is not more than approximately 95 mm. Hg.

Lithium combines with oxygen, sulphur, hydrogen, nitrogen, carbon oxides, and silicates. It forms rather stable compounds which are of a nonmetallic nature and possess relatively low melting points, or are volatile at pouring temperatures, and which possess also a low specific gravity. While the intensity with which lithium reacts is considerably less than that of the alkali metals, the heat of formation of lithium compounds is high and ranks among the highest for the respective compounds. This apparent anomaly is explained by the fact that the lithium atom and ion are of small size and that in accordance with the law of Coulomb the energy, or heat of formation, discharged is the greater the closer the reacting, or combining particles can approach each other. Table I compares the amount of oxygen and sulphur with which lithium and some other elements combine. It also gives the number of kilogram-calories which are set free by the respective reactions. While the table is self-explanatory, it may be added that lithium does not form refractory compounds as practically all other elements do which have also a relatively high affinity for oxygen.

Table I
Reaction of Oxygen and Sulphur with Various Elements*

Element	G. of oxygen which combine with 1 g. of ele- ment	Kg.-cal. set free when 1 g. of ele- ment combines with oxygen	G. of sulphur which combine with 1 g. of ele- ment	Kg.-cal. set free when 1 g. of ele- ment combines with sulphur

Refining, Degasifying, and Deoxidizing—The high affinity of lithium for practically all elements which occur as nonmetallic impurities and gases in metals and alloys permits the use of lithium as a highly efficient scavenging agent. Lithium may be applied either as lithium metal or diluted with the metal to be treated, or alloyed with an alkali earth metal. These lithium-alkali earth alloys, of which the 50/50 and 30/70% lithium-calcium alloys have been produced in commercial quantities, are in many instances more effective than lithium or the alkali earth metal alone. Furthermore, the lithium-calcium alloys are of high purity, can be handled with great convenience, and cost less than lithium.

*Consultant, New York.

The treatment of molten metals and alloys with lithium and lithium-calcium alloys is carried out in the furnace or in the ladle. In applying the treatment, it should be borne in mind that the specific gravity of lithium is as low as 0.5, so care should be taken to prevent the lithium or lithium-calcium alloy from rising to the surface of the molten mass. In the case of chromium alloys, the ladle should be covered as the reaction is rather violent. In practically all other instances, the treatment properly applied is carried out with convenience and in a simple manner similar to the application of the conventional phosphorizer in treating copper and copper alloys.

Due to the low equivalent weight of lithium (6.94), the amount of lithium or lithium-calcium alloys sufficient for the treatment is often as low as 0.005% lithium. Of course, the percentage required for the treatment will depend on the degree of purity of the metal or alloy to be treated.

Lithium as an Alloying Element—Lithium alloys readily with a number of light and heavy metals, including silicon. No alloys of lithium are known with metals of the iron and platinum groups. In the case of copper, it is doubtful whether true alloys are formed if more than 0.1% lithium is present in the copper. Silver, however, alloys with lithium and two intermetallic compounds of silver with lithium have been determined.

In a number of metals, the solid solubility of lithium is greater than that of other alkali and alkali earth metals. Typical examples are aluminum and lead. If the addition of lithium is kept within the solid solubility range, it strengthens and toughens the matrix, producing improved strength, improved elastic properties, and greater hardness. Should the percentage of lithium added exceed the solid

solubility, precipitation and age hardening occur and the physical properties of the base metal or alloy are further improved. The effects produced are similar to those observed on alloys containing magnesium and magnesium silicide. The best known examples for this type of lithium alloys are zinc die casting alloys containing less than 0.1% Li. Still higher additions of lithium, from 1-2% upward, embrittle the alloy due to the formation of intermetallic compounds of lithium with other constituents of the alloy.

The intermetallic compounds of lithium are numerous and interesting in several respects. Table II lists the intermetallic compounds which have been investigated up to 1937. From Table II, it becomes apparent that many of these intermetallic compounds are rather stable and have well defined melting points which range from approximately 450 to approximately 1150°C. Of special interest are the compounds LiHg, with a melting point of 600.5°C., and Li₃Bi, with a melting point of 1145°C. The intermetallic compounds of lithium have been of great service in investigations concerned with the nature and characteristics (atomic arrangements and physico-chemical properties) of intermetallic compounds in general. Nothing is known yet regarding the constitutional diagrams of other metals with stable intermetallic compounds of lithium.

Lithium Metal—The metal is silvery white, softer than lead, and tarnishes quickly upon exposure to the atmosphere. It must be kept in air tight containers or under kerosene. If exposed to moist atmosphere, Li₃N is slowly formed. Nitrogen penetrates solid lithium metal, forming the nitride. Lithium metal is produced in commercial quantities by means of electrolysis of fused LiCl in a mixture of chlorides. Specific gravity: 0.534; melting point: 186°C; purity: 99.5%+.

Lithium-Calcium Alloys—This alloy is silvery white, metallic luster, hard and brittle from about 50% lithium downward. The 25% Li-75% Ca alloy is as brittle as glass and can be finely ground (under oil). It must be kept in air tight containers or under kerosene. Lithium-calcium alloys react more slowly with the atmosphere than lithium. The 50-30% lithium, balance calcium, alloys have a melting range of about 230-260°C. The specific weight of these alloys is approximately 0.8-1.2, depending on the lithium content. The 50/50 and 30/70% alloys have been produced in commercial quantities by electrolysis of the fused chlorides.

Lithium-Copper—Lithium-Copper is a high conductivity, high density alloy possessing deep drawing properties and containing residual lithium and calcium in minute amounts. It is produced^a by treating molten electrolytic, or other copper of equivalent purity with a 50% lithium-50% calcium alloy in small, controlled amounts. The process is carried out in conventional melting and casting equipment. The casting can take place in the presence of air as some of the residual lithium alloy vaporizes and envelopes the stream of molten copper, thus preventing re-oxidation. The process is flexible and permits of producing oxygen-free copper, as well as so-called low oxygen copper by leaving residual oxygen in the copper in controlled and predetermined, minute amounts. About 180 grams of the lithium alloy per ton of copper sufficiently deoxidize copper which has been poled to approximately 0.025% oxygen. In case of overpoled copper, the treatment produces likewise satisfactory results since the lithium-calcium alloy readily reacts with hydrogen forming rather stable salt-like hydrides which are insoluble in copper.

Lithium-Copper has the following properties:

Conductivity, I.A.C.S. ^a	101.5% ± 0.5
Number of bends after annealing in air ^b	18-24
Number of bends after annealing in hydrogen ^b	16-24
Density, as cast ^c	8.92
Izod impact (air) ^d	10-13 (10.5 av.)
Izod impact (hydrogen) ^d	10-13 (10.9 av.)
Tensile strength, ^a psi	31,500 to 36,500
Elongation, % in 2 in. ^a	72-60
Residual lithium, %, approx. ^e	0.005-0.008
Residual calcium, %, approx. ^e	0.005-0.01

^aElectrical conductivity, tensile strength and elongation determinations made on wire having a diameter of 0.325 in., annealed in salt-peter at 1050°F.

^b0.08 in. wire annealed 30 min. at 1550°F. in air, or in hydrogen, respectively.

^c3 in. billets, top (shrinkage) cropped off, used for density determinations by immersion method. One-third of the billets had a density of 8.96, the other two-thirds as shown above.

^dIzod impact V-notch 0.080 in. deep, 0.325 in. wire. Energy of blow: 20 ft. lb. Specimens annealed 30 min. at 1550°F. in air, or in hydrogen, respectively.

^eDetermined by gravimetric method against standard samples of known compositions containing Li and Ca percentages of same magnitude.

Lithium and Lead—The solid solubility of lithium in lead is more than 0.06 and less than 0.09%, by weight (about 6-8 times greater than calcium). (At room temperatures, 70 atoms of lithium are soluble in the same number of lead atoms as 1 atom of calcium). This high solid solubility of lithium is used to advantage in lead-base bearing alloys and in workable and extrudable lead and lead alloys. The addition of lithium hardens lead-base bearing alloys. These alloys possess a relatively high hardness at elevated temperatures, high resistance toward deformation, and satisfactory wearing qualities as journal bearings, and the like.⁴ The percentage of lithium in lead-base bearing alloys is approximately 0.04%.

Workable and extrudable lead and lead alloys containing lithium have about twice the strength of lead. The increased strength and higher hardness do not appreciably reduce the ductility. The percentage of lithium in high strength lead alloys ranges from about 0.01-0.03%. Up to a lithium content of approximately 0.025%, the corrosion resistance is quite satisfactory.

Magnesium Industry

By W. G. Harvey*

Magnesium was isolated as a metallic element and some of its properties determined as early as 1830. Commercial production however was not attempted until the beginning of the twentieth century. Its outstanding characteristic is its lightness with its specific gravity of approximately 1.74 or approximately two-thirds that of aluminum. It is the lightest commercial metal and the increase in production which has occurred in recent years can be attributed to this characteristic and the demand for weight saving where lightness in portable and moving equipment is essential.

Occurrence—Magnesium does not occur in nature as a metal but in combination with other elements it constitutes approximately 2% of the earth's crust. The minerals are numerous and widely distributed. As a source of metallic magnesium, the only ones of importance are magnesite, dolomite, carnellite, and certain natural salt brines containing magnesium chloride. The latter occur in several locations in the United States. They are at present the chief source of the metal produced in this country. From them a pure magnesium chloride can be obtained which is responsible for the high commercial purity of the present day production.

Extraction Methods—Electrolytic methods are the electrolysis of magnesium oxide in a mixture of molten fluorides and the electrolysis of molten magnesium chloride either alone or mixed with other fused chlorides to lower the melting point and obtain a lower operating temperature. Magnesium chloride as a base material may be obtained by either chlorinating magnesite or dolomite or by separating it from the natural sodium chloride brines in which it at times occurs. The latter method produces a metal with a purity in excess of 99.8%. The production in the United States in 1937 was in excess of 4,000,000 pounds.

Principal Products—Pure magnesium is available in the form of metallic ingots of several sizes; in the form of powder, wire, ribbon, and extruded strip. The magnesium alloys are available in the form of sand, permanent mold, and pressure die castings; as extruded round, square, hexagonal, and rectangular rod, and special shapes; in the form of rolled plate and sheet; and as hot pressed forgings.

Alloys—The mechanical strength of pure magnesium is not high and it is therefore unsuitable for applications where more than moderate stresses are involved. Satisfactory mechanical properties are obtained by alloying the pure metal with small amounts of other metals. With the exception of iron, chromium and to a limited extent, manganese, magnesium alloys with most of the common metals. The majority of these do not form attractive combinations and the ones which do produce satisfactory strength and forming properties are those containing aluminum or zinc or both. These alloying ingredients amount in general to less than 10% so that the magnesium alloys of commerce contain in excess of 90% magnesium. Table I gives the composition of the principal magnesium alloys used for various products.

Table I
Typical Composition of Magnesium Alloys

Aluminum, %	Zinc, %	Manganese, %	Magnesium	Characteristic Use
6.0	3.0	0.3	Balance	Sand, permanent mold, and pressure die castings
10.0	none	0.2	Balance	Sand, permanent mold, and pressure die castings
8.5	0.5	0.2	Balance	Extruded rod, shapes, and press forgings
6.5	0.75	0.3	Balance	Extruded rod, shapes, and press forgings
4.0	none	0.3	Balance	Rolled sheet and plate
none	none	1.5	Balance	Rolled sheet and plate

Fabricating Methods—Magnesium alloys react with moisture at or above their melting points and sand castings, for instance, cannot be successfully made in the green sand molds employed by most foundries. It has been found necessary to incorporate inhibitors in the sand to prevent this reaction and a number of these are effective. Among the best are sulphur, boric acid, ethyl glycol, ammonium fluoride salt or combinations of these substances. A small amount of the inhibitor thoroughly mixed with the green sand is sufficient. Some modification of standard

*American Magnesium Corp., Cleveland.

casting methods must also be employed to compensate for the lighter weight of the molten metal. This is accomplished by employing more gates and risers and making all of these of greater cross section.

Most of the magnesium alloys employed for casting are capable of heat treatment with improvement in mechanical properties and this procedure is followed when the castings are to be used for highly stressed applications.

The magnesium alloys can be extruded into practically any shape for which die equipment can be constructed. The alloys are plastic within the range of 500-650°F. and at this temperature can be pressed into dies producing hot pressed forgings.

Sheet rolling methods employ an initial breakdown of either large cast ingots or extruded slabs at an elevated temperature. This operation reduces the slabs to approximately $\frac{1}{4}$ in. thickness. Rolling is continued by the hot slabbing until the thickness reaches $\frac{1}{8}$ - $\frac{1}{16}$ in. Further reduction is accomplished by cold rolling. This cold rolling produces satisfactory mechanical properties and surface finish. It is necessary to anneal the sheet frequently during the cold rolling. Present practice will produce sheet approximately 60 in. wide by 144 in. long down to 9 B. & S. gage; 30 in. wide by 144 in. long down to 20 gage; and 20 in. wide by 72 in. long in 30 gage.

Uses—There are a number of uses for pure magnesium based on its chemical properties. In the form of ingot it is an excellent deoxidizer for such metals as brass, bronze, and nickel silver. Due to its affinity for oxygen and nitrogen it removes these substances from nonferrous melts with the formation of light magnesium oxide which, rising to the surface, can be skimmed off. It is particularly useful in the nickel industry through its ability to reduce nickel sulphide and render the nickel malleable. The quantity of magnesium required for this purpose is small and varies from 0.05-0.2%.

Magnesium is also an important constituent in the alloys of other metals. A number of the high strength aluminum alloys contain from 0.2% to as high as 10.0% magnesium. In the form of powder, magnesium is used in many types of pyrotechnics for photography; for marine and railroad signals, and for military applications. Shavings and coarse powder are used for the synthesis of certain organic chemicals by the Grignard reaction. Rolled sheet is used in certain forms of dry rectifiers for changing alternating to direct current.

While these uses for the pure metal were responsible for the starting of the magnesium industry they were not sufficient to warrant the present day production. It is the combination of high strength and lightness, combined with good machinability which can be obtained in castings; in extruded rod and shapes which account for the increasing growth of this industry.

In the form of sand and die castings; as extruded rod and rolled sheet the magnesium alloys are used in many industrial applications. Practically all of these uses take advantage of the combination of light weight with strength and excellent machinability. The magnesium alloys have approximately two-thirds the weight of aluminum and one-fourth the weight of brass. Commercial uses for the products are extensive and the following are given as typical examples. In aircraft, castings are used for engine crankcases, accessory drive housings, oil pumps, intake manifolds, for landing wheels, engine starters and for many parts of the airplane. In high speed equipment they are used for reducing the weight of the moving parts of bread slicers, textile equipment parts, packaging equipment, envelope folding machines, cigarette machines, and other pieces of equipment of this general nature. Magnesium alloy products are also useful in reducing the weight of portable equipment, such as foundry flasks, patterns and match plates; for drilling equipment and for many types of portable tools.

Statistics—The consumption of magnesium alloy products for the years 1934, 1935, and 1936 are given in Table II which has been compiled from statistics published by the United States Department of the Interior.

Table II
Magnesium Products in Pounds Produced in the United States

	1934	1935	1936

Constitution of Magnesium-Aluminum Alloys

By H. E. Bakken* and R. T. Wood†

The magnesium-aluminum system was first studied by Boudouard.¹ The earliest accepted constitution diagram was determined by Grube.² The comprehensive work of Hanson and Gayler³ greatly advanced the understanding of the magnesium-aluminum system. Since the publication of the Hanson and Gayler diagram, other investigators have suggested modifications, notably to that part of the diagram pertaining to the solid solubility of aluminum in magnesium. Except, however, for relatively minor changes in the shape and position of the line of solid solubility of aluminum in magnesium, the diagram of Hanson and Gayler is at present considered authoritative by most metallurgists.

The magnesium-aluminum system cannot be considered a simple one, as it contains two compounds and three eutectics. Each metal is appreciably soluble in the other in the solid state and the compounds also form solid solutions. The diagram

Fig. 1—Magnesium-aluminum constitution diagram (Hanson and Gayler). Solid solubility line according to Schmidt and Spitaler.

shown in Fig. 1 is essentially that of Hanson and Gayler³ with the exception that the line of solid solubility of aluminum in magnesium has been changed to conform to the data of Schmidt, Seliger and Siebel. In the modified form the solid solubility of aluminum in magnesium is placed at 12.1% at the eutectic temperature (436°C.) and 2.6% at 150°C.

The scope of this discussion is limited to the magnesium rich portion of the system. Referring to Fig. 1 it will be seen that the liquidus falls from 651-436°C., the freezing point of the eutectic, as the aluminum content increases from 0-32%. The liquidus is nearly a straight line. At the eutectic composition, 32% aluminum and 68% magnesium, the liquidus and solidus coincide. In an alloy composition of about 12% aluminum the freezing begins at 575°C. and is complete at 436°C. As the composition approaches pure magnesium the temperature difference between the initial freezing and complete solidification decreases, and when pure metal is reached the liquidus and solidus lines coincide.

The area below the solidus, between the eutectic and pure metal, consists of two different structures. Between the eutectic point and the line marking the limit of solid solubility of aluminum in magnesium a heterogeneous mixture of eutectic and aluminum dissolved in magnesium occurs. Between the solid solubility line and pure magnesium a homogeneous solution of aluminum in magnesium forms.

It will be seen from Fig. 1 that about 2% of aluminum is probably soluble in magnesium at room temperature. Archer,⁴ by means of hardness determinations in aging experiments, concluded that the limit of solid solubility at room temperature is between 5 and 6%. Meissner⁵ states that an alloy of 7% aluminum is subject to age hardening while one containing 5% aluminum is not. Gann and Winston⁶ believed the solubility to be 6% or less at room temperature. A careful metallographic study of the line of solid solubility of aluminum in magnesium was made by W. Schmidt and Spitaler⁷ which indicated that about 7% aluminum is soluble at room temperature. Bakken and Wood corroborated this figure and Gann also, in general, agreed with the work of Schmidt and Spitaler.

Saldau and Zamotorin concluded after a metallographic study involving fairly long periods of annealing that the solid solubility of Al in Mg is 12.6% by weight at the eutectic temperature of 436°C. and 6.08% at room temperature. Although Saldau and Zamotorin found the solid solubility of Al in Mg did not change from

*Asst. Director of Research, Aluminum Research Laboratories, New Kensington, Pa., and †Metallurgist, American Magnesium Corp., Cleveland.

room temperature to about 300°C., they considered this finding improbable from theoretical considerations and suggested the possibility that at low temperatures the precipitated particles are too small to be resolved under the microscope or that the annealing times selected were not long enough. This suggestion was verified by the work of Schmidt, Seliger and Siebel by means of precision measurements of the lattice constants. Also, Haughton and Payne by annealing a series of specimens for 32 days at 200°C. were able to resolve precipitated material in an alloy containing 3.88% Al and concluded that the solubility limit of Al in Mg at 200°C. is 3.58%. This is a fairly close check on the solubility found by Schmidt, Seliger and Siebel at this temperature. The X-ray method of investigation employed by Schmidt, Seliger and Siebel is often more accurate than metallographic and thermal methods as it is possible to detect, by measurements of the lattice, precipitated particles much smaller than can be detected by microscopic examination. These investigators worked with alloys in the form of extruded wire. After establishing the changes in the a and c axes caused by various amounts of aluminum in solid solution it was a simple matter to anneal specimens at definite temperatures for periods long enough to establish equilibrium, quench from the annealing temperature, and measure the a and c axes of the resulting solid solution. Reference to the curves established by plotting the lattice parameters against concentrations of aluminum in solid solution would then give the actual amount of aluminum in solution in the specimen in question at the annealing temperature used. It was found that the contraction of the a and c axes of the magnesium lattice is a straight line function of the atomic per cent of aluminum in solid solution. The a axis contracts from 3.201 Å units at 0% aluminum to 3.159 Å units at 11 atomic per cent aluminum, while the c axis contracts from 5.201-5.129 Å units. The ratio c/a is given as 1.625 for pure magnesium and 1.6286 for the alloy containing 11 atomic per cent aluminum in solid solution.

The vapor pressure of the magnesium rich aluminum alloys is comparatively high. For all practical purposes the vapor pressure of these alloys may be considered the same as that of pure magnesium. At compositions as high as 12% aluminum the vapor pressure at 700°C. is above 0.3 mm. of mercury. This forms the basis of a refining and scrap recovery process. Contrary to the work of Berry,¹⁰ who found that the compound MgZn₂ could be distilled without decomposition, there is no evidence that either the compound Al₂Mg₃ or AlMg₂ can be either distilled or sublimed as such. There is some experimental evidence indicating that under carefully controlled conditions of condensation the compound MgZn₂ does not distill without decomposition. Several years experience in refining magnesium scrap containing appreciable amounts of aluminum have shown that the magnesium content of the sublimate will not vary a great deal from 99.96%.

The electrical conductivity, temperature coefficient of resistance and thermoelectromotive force of magnesium-aluminum alloys have been studied by Pecheux⁴ and Broniewski.⁵ Mehl⁷ has also reported the temperature coefficient of resistance and thermoelectromotive force of a series of alloys containing from 31-50.25% magnesium.

Constitution of Magnesium-Copper Alloys

By John A. Gann* and Manley E. Brooks*

Boudouard¹ was the first to investigate the magnesium-copper system and claimed to have identified three compounds (Mg_2Cu , $MgCu$, and $MgCu_2$) and four eutectics. Although his thermal analysis study was supplemented by microscopic examination and selective solution in dilute HCl, his work was somewhat sketchy and has not been completely verified by later investigators. Urasow² and Sahmen³ conducted thermal analysis studies over the entire magnesium-copper system and

Fig. 1—Magnesium-Copper Constitution Diagram.

their results are in substantial agreement. Sahmen likewise examined these alloys microscopically. They identified the compounds Mg_2Cu and $MgCu$, but not Boudouard's reported compound $MgCu$. No solid solutions were reported by any of these investigators.

Stepanow⁴ determined the electrical conductivity of the magnesium-copper alloys at 25° and 100°C. and also the temperature coefficient of electrical conductivity. The results obtained were in good agreement with the diagrams of Urasow and Sahmen except for approximately 4% (10 atomic per cent) solid solubility of magnesium in copper. Stepanow felt that the earlier investigators had failed to find this solid solubility because of the low rate of diffusion in these alloys.

Based on metallographic examinations, Hansen⁵ concluded that 0.4-0.5% of copper is soluble in magnesium at 485°C. and less than 0.2% at room temperature. Jenkin⁶ conducted similar investigations and concluded that the solid solubility of copper in magnesium at room temperature was approximately 0.02%. Gann⁷ likewise showed that the solid solubility of copper in magnesium was low but made no direct determinations of the absolute value.

Runqvist, Arnfelt, and Westgren⁸ confirmed the existence of the two compounds Mg_2Cu and $MgCu$, by means of X-ray investigations. Grime and Morris-Jones⁹ made an X-ray diffraction study of the entire magnesium-copper system and confirmed the findings of Stepanow except for a range of solid solution extending (probably 2-3%) on both sides of the $MgCu_2$ compound, and for a 3% solid solu-

*The Dow Chemical Co., Midland, Mich.

bility of magnesium in copper as compared to Stepanow's 4%. No evidence was found of a solid solution of copper in magnesium, thus confirming Jenkin's low solid solubility limit rather than the higher values of Hansen.

Fig. 1 represents the most recent and also the most accurate constitutional diagram of the magnesium-copper system as constructed by Jones¹⁰ from thermal analysis and metallographic investigations. He confirmed the existence of the two compounds Mg_2Cu and $MgCu_2$, of three eutectics, and of solid solutions at either end of the diagram. Magnesium was shown to dissolve 0.03% of copper near the eutectic temperature and 0.02% at room temperature, while copper dissolves 2.6% of magnesium at 700°C. and 2.1% at room temperature. Jones was unable, however, to substantiate the findings of Grime and Morris-Jones relative to solid solutions on either side of the $MgCu_2$ compound and concluded that this compound does not form solid solutions with either magnesium or copper. The thermodynamic analysis of Jeffrey¹¹ is in complete agreement with the metallographic work of Jones, and shows that the liquid phase and the solid solutions have the simplest possible constitution, namely, monoatomic molecules of copper and of magnesium.

Constitution of Magnesium-Manganese Alloys

By H. E. Bakken* and R. T. Wood†

General—The history of this alloy system is meager, most of the information available being obtained since 1927. No complete investigation of the equilibrium relations between magnesium and manganese has been made up to the time this is written and there is considerable doubt as to the exact constitution of these alloys. For instance, it is not definitely known whether the second phase that appears in the structure of alloys rich in magnesium containing from 1-3% manganese is a compound or metallic manganese. W. Schmidt¹ believes that it is an intermetallic compound but Gann² feels this phase is elemental manganese and points out that it occurs as "small blue gray particles scattered through the primary magnesium crystals, occasionally in clusters but seldom at the grain boundaries."

W. Schmidt states that as early as 1874 Terrell readily obtained a magnesium-manganese alloy by reducing manganese chloride with magnesium. The properties of the alloy obtained by Terrell were not described. Little else on the subject appears in the literature until 1921 when a patent on the process of making magnesium-manganese alloys was granted to W. R. Veazey.³ This process involved the reduction of manganese chloride in a bath of magnesium. Veazey stated that

alloys containing as high as 8% manganese can be obtained by this method. Alloys containing slightly more than 4% manganese have been made in the laboratory by direct alloying of metallic manganese with magnesium at a temperature of approximately 1100°C. under pressure in an atmosphere of argon.

Fig. 1—Partial magnesium-manganese constitution diagrams. Left, by Ruhrmann; right, by Schmidt, Seliger and Siebel.

alloys containing as high as 8% manganese can be obtained by this method. Alloys containing slightly more than 4% manganese have been made in the laboratory by direct alloying of metallic manganese with magnesium at a temperature of approximately 1100°C. under pressure in an atmosphere of argon.

Solubility of Manganese in Magnesium—W. Schmidt examined the structure of alloys containing 1.1% manganese or less and could observe no eutectic or solid solution. Gann and Winston² state that manganese has only a limited solubility in the liquid state. Schmidt shows a diagram according to Joseph Ruhrmann indicating that the liquid solubility of manganese in magnesium falls from about 2.65% at 790°C. to about 0.5% at 675°C. The curve is extrapolated to show zero liquid solubility at the melting point of pure magnesium (651°C.). The alloy containing 2.65% manganese had a thermal arrest at 645°C.

Although W. Schmidt could observe no evidence of solid solution, Gann states that some manganese is present in solid solution and presents micrographs of cast alloys containing 0.1, 0.4, and 1.0% manganese that show a small amount of coring around the individual particles due to solid solution, which indicates the location of the manganese particles is closely associated with the original dendritic structure of the primary crystallization. Bakken and Wood found that as much as 3.2% manganese could be retained in solid solution and Pearson⁴ concluded that more than 2.7% manganese is soluble in the solid state.

X-Ray Evidence—The most recent and authoritative work on the solid solubility of manganese in magnesium is that of E. Schmidt with H. Seliger and G. Siebel.⁶ This investigation was made with the aid of a precision X-ray spectrometer. The solid solubility at 645°C. was established at 3.3% and decreases to practically zero at 200°C. These investigators also report that the lattice parameters *a* and *c* of the magnesium crystal are decreased linearly with increasing atomic percentages of manganese in solid solution.

*Asst. Director of Research, Aluminum Research Laboratories, New Kensington, Pa., and †Metallurgist, American Magnesium Corp., Cleveland.

Construction of the Diagram—If the diagrams of Ruhrmann and E. Schmidt, Seliger and Siebel are correct, we have in this system a marked decrease in solubility under equilibrium conditions as the alloys containing from 0-3.3% manganese pass from the solid to the liquid state. Consider an alloy containing 2.2% manganese. At 644°C. this alloy would be a homogeneous solid solution but at a slightly higher temperature (about 650°C.) practically all the manganese would be precipitated and would not again be taken into solution until the temperature had been raised to above 770°C.

As it is impossible to construct a constitution diagram that will conform to the phase rule from the data of Ruhrmann, E. Schmidt, and others, the two diagrams are shown separately. The secondary arrests shown in the diagram according to Ruhrmann were found to exist by the present authors but not along the line drawn by Ruhrmann.

Constitution of Magnesium-Zinc Alloys

By John A. Gann* and Manley E. Brooks*

Introduction—This article deals primarily with the magnesium-rich alloys. The zinc-rich alloys are discussed more fully in another article entitled "Constitution of Zinc-Magnesium Alloys".

Based on thermal analysis studies of alloys containing up to 8.55 atomic per cent of magnesium (3.36 weight per cent), Heycock and Neville¹ concluded that the lowering of the melting point of zinc was greater with the addition of magnesium than with any other metal tried. The first investigation of the entire magnesium-zinc system is attributed to Boudouard.² By means of cooling curves he proved the existence of the compound $MgZn$, and two eutectic minima, and assumed the formation of Mg_2Zn in an effort to explain certain microscopic and selective solution data. Grube,³ Bruni, Sandonnini, and Quercigh,⁴ and Eger⁵ confirmed the work of Boudouard except that they obtained no evidence of the existence of the compound Mg_2Zn . Gorbow⁶ thought that the eutectic between zinc and $MgZn$, constituted a new compound $MgZn_2$, but this opinion has not been confirmed. No solid solutions were observed by any of these investigators.

Electrical conductivity measurements by Stepanow⁷ substantiated the work of Grube; Bruni, Sandonnini and Quercigh; and Eger, except he found a solid solubility of a few per cent of magnesium in the compound $MgZn$. Smith⁸ pointed out that the steepness of Stepanow's conductivity curve in the low percentage zinc alloys likewise indicated the possibility of some solubility of zinc in magnesium. Electromotive force measurements by Kremann and Müller⁹ showed that magnesium was made more noble by the addition of zinc, probably due to the formation of a solid solution of zinc in magnesium. The electrical conductivity and metallographic work of Peirce¹⁰ confirmed the work of earlier investigators that no solid solutions were formed at the zinc end of the diagram. His associates, Anderson and Jillson,¹¹ reported later that magnesium was probably soluble in zinc to the extent of less than 0.002% at room temperature.

The determination of the solid solubility of zinc in magnesium has formed the basis of numerous investigations and much conflicting data. Stoughton and Miyake¹² concluded from their hardness and microscopic work that more than 10% zinc will dissolve in magnesium at the eutectic temperature and their aging experiments indicate that this solubility decreases to less than 5% at room temperature. Metallographic investigations by Schmidt¹³ showed that approximately 6% of zinc is soluble in magnesium at the eutectic temperature and 1.8% at room temperature. Tensile and hardness tests by Meissner¹⁴ conducted on alloys aged at various temperatures confirmed the perpendicularity of Schmidt's solid solubility curve up to 100°C. The absence of age hardening on a magnesium alloy containing 1.7% of zinc, as reported by Hansen,¹⁵ likewise confirmed the low temperature solid solubility. Metallographic studies by Chadwick¹⁶ indicated that the solid solubility of zinc in magnesium at the eutectic temperature was between 3.2 and 5.4 atomic per cent (8.2 and 13.3 weight per cent) and he assumed it to be about 5 atomic per cent (12.4 weight per cent). Electrical conductivity investigations by Grube and Burkhardt¹⁷ indicated that approximately 6.5% of zinc are soluble in magnesium at the eutectic temperature and 3.5% at 250°C. Schmidt¹⁸ stated that precision X-ray investigations gave 8.4%

Fig. 1—Magnesium-Zinc Constitution Diagram.

*The Dow Chemical Co., Midland, Mich.

as the solid solubility of zinc in magnesium at the eutectic temperature and that this decreased to something over 1% at room temperature. Schmid and Seliger¹⁸ elaborated on this report and gave the solid solubility curve for the temperature range of 150-344°C. Schmid and Seliger, and Schmidt and Hansen are in excellent agreement on the solid solubility of zinc in magnesium throughout the temperature range of 150-250°C. Schmid and Seliger's value of 8.4% for the solid solubility of zinc at the eutectic temperature is appreciably higher than the corresponding value of Schmidt and Hansen, but is in good agreement with the lower value of Chadwick's 8.2-13.3% range and is substantiated by unpublished data from the laboratories of The Dow Chemical Company which indicate that approximately 8% of zinc is soluble in magnesium at the eutectic temperature.

The three most complete investigations of the magnesium-zinc system agree in most respects but differ chiefly in regard to the ability of the intermetallic compounds to form solid solutions. Chadwick¹⁸ in 1928 and Hume-Rothery and Rounsefell²⁰ in 1929 constructed constitutional diagrams based on thermal analysis and metallographic studies. The former reported solid solubility zones on both sides of the $MgZn_2$ compound and on the zinc-rich side of the $MgZn$ compound; while the latter concluded that neither compound entered into solid solution. Grube and Burkhardt¹⁷ in 1929 determined the electrical conductivity and thermal expansion of these alloys and confirmed the existence of the solid solubilities reported by Chadwick, and in addition claimed that the compound $MgZn_2$ formed a solid solution with excess of magnesium. Both $MgZn$ and $MgZn_2$ are formed by peritectic reactions and appear to undergo polymorphic transformations at somewhat lower temperatures.

Fig. 1 shows the constitution diagram of the magnesium-rich alloys according to Chadwick, modified to include the $MgZn$ compound reported by Hume-Rothery and Rounsefell, the polymorphic transformation of this compound at 260°C, as reported by Grube and Burkhardt, and the solid solubility of zinc in magnesium as reported by Schmid and Seliger near the eutectic temperature and by Schmidt and Hansen at lower temperatures. This portion of the diagram shows a simple eutectiferous system of alloys except for the solid solubility of zinc in magnesium and the polymorphic transformation of the $MgZn$ compound.

Physical Constants of Magnesium

By Cyril S. Taylor* and Junius D. Edwards*

Atomic Weight—Magnesium has the atomic number 12. Its atomic weight is 24.32. The atomic volume is 14.0 cc. Magnesium has three isotopes; their mass numbers in order of the intensities of the mass spectrum lines are 24, 25, and 26.^{1, 2}

Crystal Form—Magnesium crystallizes with a hexagonal close packed lattice. The unit cell has the following dimensions^{3, 4}: The side of the hexagonal base "A" = 3.2030×10^{-8} cm., the height of the hexagonal prism "C" = 5.2002×10^{-8} cm. The axial ratio c/a = 1.6235.

Density—The density at 20°C. of magnesium of varying purity and form is given in Table I.

Table I
Density of Magnesium

Purity of Magnesium, %	Density at 20°C.	Form of Sample	Authority
99.99	1.7388	Extruded bar $\frac{1}{2}$ in. in dia.	(5)
99.99	1.7388	Same as above, but annealed 2.5 hr. at 400°C.	(5)
99.95	1.7381	Extruded bar $\frac{1}{2}$ in. in dia.	(5)
99.94	1.7386	Extruded bar $\frac{1}{2}$ in. in dia.	(5)
99.90	1.7381	Extruded bar $\frac{1}{2}$ in. in dia.	(5)
99.90	1.737	As cast	(6)

No change in density was observed as a result of annealing the purest metal for 2.5 hr. at 400°C. The density of 99.99% magnesium at and above its melting point has been determined by Edwards and Taylor.⁵ The values are given in Table II. The values given were taken from the complete density curve from 20-750°C.

The values for density are numerically equal to the specific gravity of the metal when referred to the weight of water at 4°C. Magnesium at 70°F. weighs approximately 108.5 lb. per cu.ft. (1.7388×62.428). In passing from the liquid to the solid state at the freezing point, there is a contraction in volume amounting to approximately 4.2%.

Table II
Density of Magnesium at and Above Its Melting Point⁵ 99.99% Purity

Temp., °C.	Density, g. per cc.	Remarks
650	1.642	At melting point, solid (calculated)
650	1.572	At melting point, liquid (extrapolated)
673	1.562	Measured
700	1.544	Interpolated

Table III
Average Coefficients of Expansion of Magnesium⁶

Temperature Range, °C.	Average Coefficients of Expansion per °C.		
	Cast Magnesium	Extruded Magnesium	Average
	$\times 10^{-6}$	$\times 10^{-6}$	$\times 10^{-6}$
20-100	26.1	25.8	26.9
100-200	27.8	27.6	27.7
200-300	29.7	29.5	29.6
300-400	31.6	31.5	31.5
400-500	33.6	33.4	33.4
20-200	27.0	26.8	26.9
20-300	28.0	27.8	27.9
20-400	28.9	28.8	28.8
20-500	29.9	29.7	29.8

Compressibility—The compressibility of magnesium or percentage change in volume with unit change in pressure of 1 megabar (0.987 atmospheres or 14,504 psi.) is approximately 2.9×10^{-6} at room temperature.⁷

*Aluminum Research Laboratories, New Kensington, Pa.

Thermal Expansivity—According to measurements of the Bureau of Standards by Hildner and Sweeney,⁸ the average thermal expansivity of cast and extruded magnesium (99.99% purity) is given by the following equation, for the temperature range 20-500°C., L_0 is the original length and L_t the length at temperature, t :

$$L_t = L_0 [1 + (24.80t + 0.00961t^2) 10^{-6}]$$

The average expansion coefficients for magnesium for a variety of temperature ranges are given in Table III.

Freezing Point—The value adopted by the Bureau of Standards⁹ for the freezing point of magnesium is 651°C.

Specific Heat—The specific heat is defined as the quantity of heat necessary to raise 1 g. of a given substance through a temperature of 1°C. Specific heat varies with temperature, and is usually expressed as a mean or average value over a definite range of temperature. The values for the mean specific heat of magnesium over several ranges of temperature are given in Table IV.

Table IV
Mean Specific Heat of Magnesium

Temp., °C.	Specific Heat	Authority
-190 to + 17	0.2048	Schlimpf ¹⁰
	0.2090	Behn ¹¹
-185 to + 20	0.2220	Nordmeyer and Bernoulli ¹²
-79 to + 17	0.2284	
	0.2311	Schlimpf
	0.2330	Brunner ¹³
-17 to + 100	0.2495	Behn
	0.2460	Brunner
	0.258	Voigt ¹⁴
150 to 250	0.258	Awberry and Griffiths ¹⁵
250 to 350	0.264	
350 to 450	0.280	
450 to 550	0.296	
550 to 625	0.300	
650 to 750 (liquid)	0.266	

Latent Heat of Fusion—The latent heat of fusion of magnesium, or the heat absorbed in converting a unit weight of the metal from solid to liquid at its melting point without changing the temperature is 46.5 g.-cal. per g. of metal (83.7 B.t.u. per lb.).¹⁶

Boiling Point—According to Hartmann and Schneider,¹⁶ the boiling point of magnesium is 1107°C. Leitgeb¹⁷ has determined the boiling point to be $1097 \pm 3^\circ\text{C}$.

Vapor Pressure—Vapor pressure values for magnesium at various temperatures are given in Table V. Millar's values are estimated from a boiling point of 1120°C.; Hartmann and Schneider's values are based on experimental observations.

Heat of Vaporization—The heat of vaporization of magnesium as determined by Musceleanu¹⁸ is 1700 g.-cal. per g. of metal (3060 B.t.u. per lb.). Values calculated by Richards,¹⁹ Johnston,²⁰ Hildebrand,²¹ and Hartmann and Schneider,¹⁶ range from 1300-1500 g.-cal. per g.

Critical Temperature—The critical temperature of magnesium, as calculated by Hartmann and Schneider,¹⁶ is 1867°C.

Table V
Vapor Pressure of Magnesium

Temp., °C.	Vapor Pressure Mm of Mercury	Authority
25	1.7×10^{-17}	Millar ¹⁷
300	2.5×10^{-8}	Millar
380	1.1×10^{-3}	Millar
651	2.28	Millar
750	12.	Hartmann and Schneider ¹⁶
800	26.	
850	49.	
900	94.	
950	166.	
1000	280.	

Table VI
Thermal Conductivity of Magnesium

Temp., °C.	Conductivity	Authority
0-100	0.376	Lorenz ²²
101-250	0.35	Williams ²³
18	0.376	Jones ²⁴
18	0.34	Archbutt ²⁵
18	0.38	Flusin, ²⁶ Maybrey, ²⁷ Guillet ²⁸

Thermal Conductivity—The thermal conductivity of magnesium is relatively high, being more than three times that of cast iron. The thermal conductivity of magnesium, or the amount of heat in gram-calories transmitted per second through a plate 1 cm. thick per sq. cm. of its surface when the difference of temperature between the two faces of the plate is 1°C., is given in Table VI.

Heat of Combustion—The heat of combustion of magnesium with oxygen was determined by Moose and Parr²⁹ and Franck and Hochwald³⁰ as 146,100 g.-cal. per mole ($\text{Mg} + \text{O} = \text{MgO}$), which is equivalent to 10,800 B.t.u. per lb.

Optical Properties—The reflecting power of magnesium has been determined by Coblenz³¹ and by Hulburt.³² Magnesium sheet, freshly cleaned in dilute hydrochloric acid, had a reflecting power for visible light of 82%, according to recent unpublished measurements by C. S. Taylor. Table VII gives the reflecting power of magnesium at various wave lengths.

Table VII
Reflecting Power of Magnesium

8.0	93.0	Coblenz
9.0	93.0	Coblenz

Electrical Resistivity, Conductivity—Some of the electrical properties of extruded magnesium rod are given in Table VIII. Magnesium has a volume conductivity equal to 38.6% of copper. The mass conductivity is 197.7% of copper.

The constant mass temperature coefficients of resistance for magnesium are given in Table IX.

Electrochemical Equivalent—The electrochemical equivalent for magnesium is the number of g. deposited per sec. by a current of 1 ampere or the g. per coulomb. It is equal to the atomic weight 24.32 divided by the valence 2, and the constant 96,500, or 0.12601 mg. per coulomb. In various units it is as follows:

Electrochemical Equivalent of Magnesium

Unit	Value
Mg. per coulomb.....	0.12601
Coulombs per mg.	7.9359
G. per ampere-hr.....	0.45364
Pounds per 1,000 ampere-hr.	1.0001
Ampere-hr. per lb.....	999.90

Electrolytic Solution Potential—According to standard terminology, magnesium is electronegative to the elements which it replaces in solution; the magnesium going into solution in the form of positive ions leaves the metal negatively charged.

Table VIII
Electrical Properties of Magnesium Rod
According to Taylor and Edwards

Description	Property	Value
Magnesium (extruded) 99.99%	Specific resistivity at 20°C.	4.4611×10^{-8} ohms/cm. ^a
Magnesium (extruded) 99.95%	Specific resistivity at 20°C.	4.4699×10^{-8} ohms/cm. ^a
Magnesium (extruded) 99.90%	Specific resistivity at 20°C.	4.4774×10^{-8} ohms/cm. ^a
International annealed copper standard	Volume conductivity compared with copper	100 %
Magnesium (extruded) 99.99%	Volume conductivity compared with copper	38.65%
Magnesium (extruded) 99.95%	Volume conductivity compared with copper	38.57%
Magnesium (extruded) 99.90%	Volume conductivity compared with copper	38.51%
International annealed copper standard	Mass resistivity	0.15328 ohm (m.g.)
Magnesium (extruded) 99.99%	Mass resistivity	0.07753 ohm (m.g.)
Magnesium (extruded) 99.95%	Mass resistivity	0.07768 ohm (m.g.)
Magnesium (extruded) 99.90%	Mass resistivity	0.07780 ohm (m.g.)
Aluminum, conductor grade	Mass resistivity	0.07640 ohm (m.g.)
International annealed copper standard	Mass conductivity	100 %
Magnesium (extruded) 99.99%	Mass conductivity	197.71%
Magnesium (extruded) 99.95%	Mass conductivity	197.33%
Magnesium (extruded) 99.90%	Mass conductivity	197.01%
Aluminum, conductor grade	Mass conductivity	200.70%

hence the characterization "electronegative". The single potential of magnesium (the normal hydrogen electrode being taken as zero and a solution being employed in which the metal ion concentration is normal) is very difficult to measure experimentally, and the results are not reproducible. Latimer,²⁸ from thermal data, has calculated the single potential of magnesium to be: $E^\circ = -2.40$ volts, a value which agrees fairly well with earlier calculated values.

Thermoelectric Power—The thermoelectric power of a circuit of two metals is the electromotive force produced by 1°C. difference in temperature between the junctions.

Properties of Magnesium-Aluminum Alloys (Containing Small Amounts of Manganese)

By R. T. Wood*

General—At the present time, aluminum is the most important element employed to form alloys of magnesium. Practically all of the commercial magnesium alloys manufactured in this country contain aluminum in amounts varying from 3-13%. Inasmuch as practically all commercial alloys of magnesium with aluminum contain small amounts of manganese, the data given in these pages applies to alloys containing manganese rather than pure binary magnesium-aluminum alloys.

The amount of manganese that can be retained in the alloys decreases with increasing aluminum content. Alloys with 4% aluminum usually contain about 0.35% manganese, while those with 12% aluminum usually contain about 0.10% manganese. The chief purpose in adding the manganese is to enhance corrosion resistance. It has little effect on the mechanical properties, although it does increase the proportional limit and yield strength of wrought alloys. Metallographically, the effect of the manganese constituent cannot be observed.

Fig. 1—Densities of magnesium-aluminum alloys. Fig. 2—Effect of aluminum on magnesium on the thermal conductivity. Fig. 3—Electrical resistivity of magnesium-aluminum alloys. Fig. 4—Linear contraction of magnesium-aluminum casting alloy.

show a precipitate when examined microscopically after such treatment.

The heat treatment of wrought magnesium-aluminum alloys is usually not beneficial unless more than about 9% aluminum is present, and in the range 9-13% aluminum, the solution heat treatment must be followed by artificial aging or precipitation to bring about maximum increases in tensile strength, yield strength, and hardness, which increases are at the expense of ductility. The increase in mechanical properties over those of pure magnesium brought about by the addition of aluminum and subjecting the alloys to a suitable heat treatment is remarkable. In the cast condition it is possible to triple the tensile strength, more than double the elongation, increase the yield strength seven times, triple the hardness

Because the solid solubility of aluminum decreases from 12.1% at the eutectic temperature to about 2% at room temperature, the magnesium-aluminum alloys are amenable to heat treatments involving solution and precipitation of the compound¹ Mg₂Al₃. From a practical standpoint heat treatment is most beneficial on alloys containing between 6% and 13% aluminum. All of the cast alloys in this range of composition are benefited by solution treatment, while those containing from 8% to 13% aluminum develop an appreciably greater hardness and a higher yield strength when the solution heat treatment is followed by a precipitation or aging treatment. From equilibrium data it might be expected that alloys containing from 2-6% aluminum would increase in hardness on aging at room temperature or at some elevated temperature in the range 200-300°F. However, such is not the case. An alloy containing 6% aluminum failed to show any change in properties after a solution heat treatment and room temperature aging for six years. Artificial aging at elevated temperatures for times up to 48 hours of alloys in the range 2-6% aluminum has failed to cause any worthwhile change in properties although alloys containing more than about 3.5% aluminum

*Metallurgist, American Magnesium Corp., Cleveland.

and more than double the endurance limit. In the wrought condition it is possible to double the tensile strength, triple the elongation, more than triple the yield strength, more than double the hardness and increase the endurance limit three and a half times. As the aluminum content of magnesium-aluminum alloys is increased above 5% in either the cast or wrought condition, they become less ductile until those with more than 13% aluminum are considered too brittle to use for structural purposes. When the aluminum content is increased to 30%, the alloy resembles glass in character.

Density—When aluminum is added to the maximum amount compatible with alloys of commercial usefulness (13%), the increase in density over that of pure magnesium is only about 6%. The densities of alloys in the commercially useful range are shown in Fig. 1.

Thermal Conductivity and Electrical Resistivity—The thermal conductivity of pure magnesium in the range 100-250°C.³ has been given as 0.35 in cgs. units. A more recent determination⁴ in the range 100-300°C. gives the value of 0.38 cgs. units. The addition of aluminum to magnesium progressively reduces the thermal conductivity in the manner shown in Fig. 2 until the 12% aluminum alloy has a thermal conductivity of only 0.16 cgs. units.

As would be expected in a series of alloys forming an appreciable range of solid solutions, the electrical resistivity of magnesium-aluminum alloys increases with increasing aluminum content. This relation for cast alloys and for cast alloys with all the aluminum in solution is shown in Fig. 3. A solution heat treatment causes a noticeable increase in resistivity especially in alloys containing 8-13% aluminum.⁵

Thermal Expansion—The coefficient of thermal expansion of pure magnesium in the range 0-100°C. is 0.0000259⁶ and this figure is not altered appreciably by the addition of aluminum in amounts up to 12%. There is some indication that the thermal expansion of wrought alloys is less than that of cast alloys. The value of the mean coefficient of expansion is apparently affected more by the temperature range selected for measurement than by the amount of aluminum present in the alloy. According to Scheel,⁴ the mean coefficient of linear expansion for magnesium, and hence the magnesium-aluminum alloys, from 0°C. to any temperature t may be obtained from the following equation:

$$\alpha = (25.07 + 0.00936 t) 10^{-6}$$

and the total length l_t at any temperature t may be expressed by the function:

$$l_t = l_0 [1 + (25.07 t + 0.00936 t^2) 10^{-6}]$$

Growth—In common with several other alloy systems wherein the solid solu-

Fig. 5—Tensile strength of sand cast magnesium-aluminum alloy. Fig. 6—Same as Fig. 5, but after solution heat treatment. Fig. 7—Mechanical properties of extruded metal.

bility of the solute element decreases with temperature, the magnesium-aluminum alloys exhibit, under certain conditions, the phenomenon termed "growth". Alloys quenched from a high temperature solution heat treatment have a slightly higher density than the same alloys in equilibrium at room temperature. The magnitude of this difference is small under all conditions, but is greater the higher degree of supersaturation. This change in density is not noticeable or important until the alloys contain more than 8% aluminum in solid solution. Thus with ordinary sand castings the rate of cooling is such that for all practical purposes and especially for uses at room temperature, no changes in density can be detected.

However, in chill cast alloys and alloys containing 10-13% aluminum quenched from high temperatures, the change in density that may take place in service, especially service involving elevated temperatures of 300°F. or above, is noticeable and can be measured. Probably the greatest change in density is exhibited by the 12% aluminum alloy quenched from the solution heat treating temperature. Changes in density in this alloy have been estimated by measuring the linear change in dimensions accompanying reheating to elevated temperatures. This change in dimension has been termed "growth" or "permanent growth". The total unit growth of the quenched 12% aluminum alloy amounts to about 0.00074 in. per inch. Equilibrium is practically established by heating for 50 hr. at 440°F. In the chill cast 12% aluminum alloy the total unit growth is about 0.00043 in. per inch and in this case also, equilibrium is practically established by heating for 50 hr. at 440°F. In both cases, 30 hr. at 440°F. will bring about 85% of the total growth. There have been a few instances reported of growth in service of the solution heat treated 10% aluminum alloy but several years' experience indicates that for all ordinary conditions of service including use in aircraft motors, the amount of growth exhibited by the 10% aluminum alloy is unimportant.

Casting Characteristics—The magnesium-aluminum alloys have the best foundry or casting characteristics of any of the present well-known binary magnesium alloys with the possible exception of the magnesium alloys with copper. While the fluidity and freedom from shrinkage difficulties and hot shortness of the magnesium-aluminum alloys may not be any greater than that of the magnesium-copper alloys, their superior mechanical properties and resistance to corrosion and their amenability to heat treatment make the magnesium-aluminum alloys by far the most important series of alloys from the foundry's viewpoint. The properties of an alloy that determine its suitability for foundry use are fluidity, solidification shrinkage, linear contraction from solidification temperature to room temperature, and hot shortness. The fluidity of magnesium-aluminum alloys at casting temperature increases with increasing aluminum content. Although the fluidity of the best magnesium-aluminum alloy does not equal that of many aluminum-base casting alloys, it is adequate for most purposes. Tests have shown that under practical foundry conditions and when the metal is poured into green sand molds, a pouring temperature of about 790°C. is conducive to maximum fluidity. The total shrinkage from the molten state increases with the aluminum content up to about 7 or 8% aluminum and then decreases slowly. This increase in shrinkage is offset, so far as foundry characteristics are concerned, by a decreasing tendency to "pipe" as the amount of aluminum in the alloy is increased. One of the most important properties of alloys intended for foundry use is the linear contraction after solidification, as this property determines the pattern shrinkage that must be allowed and also has considerable influence on cracking. Fig. 4, according to Bastien,* shows the variation in linear contraction with concentration of aluminum of alloys cast in sand molds. Bastien found the linear contraction for alloys cast in chill molds to be somewhat less. The pattern shrinkage allowance on patterns built especially for use with the present commercial magnesium base casting alloys should be $\frac{1}{4}$ in., but, for most castings, patterns made for aluminum alloys with a pattern shrinkage of $\frac{1}{8}$ in. will be found to be quite satisfactory.

The other factor which, together with linear contraction, exerts a determining influence on the tendency of an alloy to crack when poured into a mold of complicated design is the property known as hot shortness. The hot shortness of magnesium-aluminum alloys increases with increasing aluminum content. In this series of alloys the tendency to crack because of stresses set up by contraction decreases as the aluminum content approaches 11% and then increases slightly while the tendency to crack because of low intergranular cohesion at elevated tem-

peratures increases steadily with increasing aluminum content. These two factors tend to counterbalance each other in alloys containing less than 11% aluminum, and hence it would be expected that at some composition under 11% aluminum, the tendency to crack would be at its minimum. Foundry experience indicates that this point lies within the range 8-11% aluminum.

Mechanical Properties—In the cast condition the addition of aluminum to magnesium brings about a marked change in all of the mechanical properties. Heat treating the alloys produces an even greater change. The variations in mechanical properties of magnesium-aluminum alloys with aluminum content in both the cast condition and after a solution heat treatment are shown in Fig. 5 and 6. Still other combinations of mechanical properties may be obtained by the artificial aging of heat treated alloys containing more than about 8% aluminum. The endurance limit of magnesium-aluminum alloys increases with increasing amounts of aluminum up to at least 10% aluminum. A solution heat treatment increases the endurance limit while artificial aging following the solution heat treatment reduces the endurance limit so that it approaches that of the as cast alloy. The endurance limit of a sand cast alloy containing 10% aluminum and given a solution heat treatment is about 11,000 psi. (500,000,000 reversals). The shear strength and compressive strength increase rapidly as the aluminum content is increased from 0-4%, but from 4% aluminum to about 10% aluminum the rate of improvement in these properties is reduced and, as the aluminum content is increased over 10%, the compressive strength and shear strength tend to drop somewhat. An average figure for Young's Modulus of Elasticity for magnesium-aluminum alloys containing up to 13% aluminum is 6,500,000 psi.

Working Characteristics—In common with other magnesium base alloys, the magnesium-aluminum alloys have poor cold working characteristics and hence all wrought products are produced by some hot working process. A certain amount of bending and forming may be done cold, and sheet and wire may be reduced by cold working interspersed with frequent annealing. Magnesium-aluminum alloys containing up to at least 20% aluminum may be extruded. The hot rolling characteristics of alloys containing more than about 8% aluminum are unsatisfactory, and in this country rolled magnesium alloy sheet usually does not contain more than 5% aluminum. The hammer forging characteristics of magnesium-aluminum alloys are poor but alloys containing up to about 10% aluminum may be worked comparatively readily on hydraulic or steam presses. Under carefully controlled conditions it is possible to hammer forge these alloys containing up to about 4% aluminum.

Magnesium-aluminum alloys are most readily fabricated by the extrusion process and it is by this process that the most favorable mechanical properties are obtained. Heat treatment of wrought magnesium-aluminum alloys is usually not beneficial although it is possible to increase the yield strength and hardness of wrought alloys containing from 9-11% aluminum by suitable treatment.

Mechanical Properties—The mechanical properties of extruded magnesium-aluminum alloys are shown in Fig. 7. The endurance limit of the wrought alloys increases with increasing aluminum content up to about 8 or 8.5%, after which it remains about the same or drops off slightly as the aluminum content is increased to 10%. The endurance limit of wrought alloys containing more than 10% aluminum has not been investigated. The endurance limit of thoroughly worked extruded material containing about 8% aluminum is about 16,000 psi. (500,000,000 reversals).

Corrosion Resistance—Magnesium-aluminum alloys containing the usual amounts of manganese are perfectly stable under ordinary conditions but are not suitable for use in direct contact with salt water. In seaboard atmospheres they should be protected with paint. These alloys are not subject to intergranular corrosion and, although attacked by nearly all acids and salt solutions they are resistant to alkalis and fluorides. In general, the resistance of magnesium-aluminum alloys to salt spray corrosion increases with the amount of AlMg₂ constituent in the microstructure. Heat treatment to bring about solution of this constituent reduces the corrosion resistance to salt spray. Aging supersaturated solid solutions to cause precipitation of AlMg₂ increases the corrosion resistance in proportion to the amount of precipitate. In order to increase their corrosion resistance, most magnesium alloys are dipped in a bath containing nitric acid and sodium dichromate which produces a surface that will resist tarnish for long periods and to which paint will

adhere. The use of inhibitive primers is very desirable and those pigmented with 100% zinc chromate have been found most effective. Synthetic resin enamels have been found to be the most satisfactory for the finish coats.

Properties of Magnesium Casting Alloys

By John A. Gann*

General—Substantially all magnesium alloy castings are now produced from the Mg-Al-Mn or the Mg-Al-Mn-Zn alloys. (Die castings are generally made from a Mg-Al-Mn-Si alloy.) Aluminum is the chief added ingredient as it is more effective than any other element in improving the properties and casting characteristics of magnesium. Zinc is added in smaller amounts. It improves both the salt water corrosion resistance and the properties of the alloys, particularly in the heat treated condition. Manganese is present in all of these alloys in amounts ranging from 0.1-0.4%, that is, in amounts approximating the solubility of manganese in the liquid alloy. Manganese has little or no effect on the physical properties, but materially improves the corrosion resistance. The best combinations of properties are obtained with alloys containing 8-12% of aluminum, or of aluminum plus zinc. Alloys with less than 8% of added metal have relatively poor casting properties and low yield strength and hardness, while alloys containing more than 12% of added metal are too brittle for most purposes. The percentage of zinc must be kept relatively low in order to avoid hot shortness, particularly during heat treatment. Since copper and nickel have a deleterious effect on the corrosion resistance, all metal handling operations, particularly remelting, must be carefully controlled so as to keep these impurities at a minimum. The maximum quantities permitted by A.S.T.M. Specifications are 0.05% of copper and 0.03% of nickel.

The Mg-Al-Mn-Zn alloys are being widely adopted in this country now that they can be successfully heat treated: They bid fair to replace the older Mg-Al-Mn alloys because they offer better combinations of mechanical properties and improved corrosion resistance. The most widely used member of this series has a nominal composition of 6% Al, 0.2% Mn, 3% Zn, and balance Mg.

Nomenclature—The trade designation and society nomenclature of these alloys are given in Table I.

Heat Treatment—All of these magnesium casting alloys are amenable to heat treatment. Solution heat treatment increases the tensile strength, elongation, and impact toughness; while subsequent precipitation heat treatment, or aging, increases the yield strength and hardness at the sacrifice of the elongation and toughness. Properties intermediate between those obtained by solution heat treatment and those obtained by aging can be produced by a short time or partial precipitation heat treatment. This partial aging is not used extensively, however, because of practical difficulties encountered with furnace charges consisting of various sized castings with both thick and thin sections.

Properties—Average physical and mechanical properties of these alloys in the as-cast state and in the heat treated conditions most generally used are given in Table II.

Casting Characteristics—All of these magnesium alloys have good casting characteristics, although the technique employed differs somewhat from that used with other metals, particularly in the protective measures used in the melting and casting operations. Increasing the percentage of aluminum or of aluminum plus zinc tends to improve the fluidity. The low specific gravity of all magnesium alloys necessitates the use of generous runners and gates in order to insure proper feeding, and large risers to counteract shrinkage cracking. Pattern design calls for a shrinkage factor of $\frac{3}{8}$ in. per ft. on castings of moderate size, or $\frac{1}{2}$ in. per ft. on large castings and in those cases where normal shrinkage is hindered by bosses or internal cores. Generous fillets should be used where thin sections-join heavy sections and where the gates join the casting.

General Characteristics and Uses—Magnesium alloy castings are used chiefly in those industries where lightness and high strength-weight ratios are essential. They weigh two thirds as much as aluminum and approximately one fourth as much as iron; whereas their strength is comparable to that of aluminum alloys and varies from the same to approximately one half the corresponding values for cast ferrous metals, depending on the properties considered and the composition of the ferrous product.

S.C.—Sand Cast. H.T.—Solution Heat Treated. H.T.A.—Solution Heat Treated and Aged.

Thermal Conductivity is expressed in cgs. units 100-300°C.

Electrical Resistivity is expressed in microhms/cm² at 20°C (68°F).

Tensile Properties are obtained on A.S.T.M. 1/2 in. dia. cast-to-size bars.

Yield Strength is defined as the stress at which the stress strain curve deviates 0.2% from the modulus line.

Compression and shear values are obtained on 1/4 in. dia. specimens machined from 1 in. dia. bars.

Fatigue endurance values are obtained on R. R. Moore machine at 500 million cycles.

Modulus of elasticity of magnesium alloys is 6,500,000 psi.

Minimum values conform to A.S.T.M. Specification B30-387 where applicable.

Excellent machinability is another valuable characteristic of magnesium alloys. They can be machined at higher tool speeds and with deeper cuts than is possible with other metals. Where machining costs constitute a large percentage of the total cost of the finished part, magnesium alloy castings often become strictly competitive with those produced from basically cheaper metals.

The aircraft industry is the largest consumer of magnesium alloy castings. The important applications include motor castings, starting equipment, instrument housings, landing wheels, and miscellaneous structural supports and brackets. The portable tool industry is using increasing amounts of sand castings for handles, motor cases, and gear housings in both electric and pneumatic drills and sanders. Magnesium castings are likewise used in the reciprocating and rapidly moving parts of textile, packaging, and conveying machinery or equipment as well as in fans, blowers, and rotors. Safety device equipment includes tongs, saw guards, and safety blocks for forming presses, and die cast goggle frames. Foundry uses include flasks, pattern plates, core boxes, and jigs. Die castings are finding many applications in office equipment and household appliances. Magnesium alloy castings are being used successfully in those industries where a saving in weight results in a more economical operation of the equipment or in a saving of human fatigue.

Polishing of Magnesium Alloys for Metallographic Examination

By R. W. James*

General—Metallographic preparation of the magnesium-base alloys requires a polishing technique quite different from that ordinarily employed on the harder ferrous and nonferrous alloys. Susceptibility to surface flow and scratching, and the tendency of abrasive particles to imbed in the matrix are characteristics of magnesium alloys that must be obviated as completely as practicable by a careful preparation of the samples. The procedure suggested develops a surface suitable for the production of high magnification (500 diameters, or more) photomicrographs.

There are several methods for mounting specimens that cannot be conveniently polished by holding in the fingers. One method is to place the sample face down on a glass plate, surround it with a ring cut from aluminum tubing of proper diameter, and fill the ring with molten sulphur, dental cement, or sealing wax. Mounting materials that may induce galvanic action during polishing or etching must be avoided. This mounting method provides sufficient edge-support for the specimen to materially facilitate the high magnification examination of edge effects such as corrosion, surface imperfections, fractures, or artificial coatings.

If the equipment is available, the metallurgical mounting press offers the most satisfactory method of preparing mounted specimens. A variety of mounting media, including Bakelite, Vinylite, Tenite, and Leucite, are commercially obtainable in a wide range of hardnesses and transparency. The mounting press method, by virtue of the heat and pressure employed, assures a more intimate contact between the specimen and the supporting medium, produces a mounting that will not chip off and foul the wheel and, by the proper selection of mounting media, results in a specimen mounting that permits maximum definition on a flat field.

A satisfactory method of preparing thin specimens for examination in cross section or inspection of surface films is to bolt a number of flat pieces together, using heavier retainer plates having about the same polishing characteristics as the specimens next to the bolt head and the nut.

The rough preparation of the specimens for polishing and the subsequent finishing operations are identical in all cases, irrespective of the mounting method.

Preparation for Microscopic Examination—The metallographic sample is removed from the article in question with a hand hack saw or by any other suitable method. Saw marks or other roughness on the face to be polished are removed with a "regular cut" file. The surface may be further improved by holding the specimen in the hand and drawing it several times over a "second cut" file held motionless on the bench by the other hand. This tends to eliminate the slight curvature that results from moving the file over the rigidly-held specimen. During the rough preparation of a sample, care should be exercised not to clamp the piece too tightly in the vise or subject it to unnecessary impacts that may produce mechanical twinning and subsequently lend confusion to the interpretation of the microstructure.

After the pieces are filed smooth, they are rubbed successively on No. 1, 00, and 0000 emery papers, the specimen being rotated 90° in passing to each finer abrasive to remove the scratches from the preceding paper. Magnesium and its alloys have little tendency to foul the papers but, should this difficulty be encountered, a small amount of kerosene poured on the paper will loosen the obstructing particles, promote a cleaner cutting action, produce a smoother specimen, and add appreciably to the life of the abrasive paper. The use of kerosene will also hold down the magnesium dust which may become objectionable if a large amount of grinding is being done.

If a microtome is available, and the blade is in good condition, rough-sawed metallographic specimens of magnesium alloys may be cut down to a plane surface suitable for taking immediately to the fine polishing wheels without the intermediate preparations recommended above.

Samples are taken from the No. 0000 paper, or the microtome, to a wheel covered with a fine quality broadcloth. In the first operation on this wheel, a dry abrasive known as 65F alundum (Al_2O_3) is sprinkled on the cloth and worked into a thin paste by the addition of water and manipulation with the finger tips. The wheel is then rotated at about 500 r.p.m. and the specimen applied to it until the scratches remaining from the previous operation are just barely removed. Too much

*Aluminum Research Laboratories, Cleveland

pressure or excessive time in any of the finishing steps on the cloth wheels will cause the harder constituents (principally Mn and Mg₂Si) to stand out in undesirable relief. When the scratches have been removed, the cloth is washed free of abrasive and a good lather is worked up by holding a piece of soap against the rotating wheel. The speed is decreased to 300 r.p.m. and the specimen, held lightly against the cloth, is slowly rotated counter to the directional motion of the wheel. In this operation a high reflectivity should be developed by the removal or "washing out" of abrasive (alundum) particles embedded in the magnesium matrix. It is imperative that a high purity soap be used to prevent corrosive attack on the specimen. Ivory soap has been found quite satisfactory.

The final polishing wheel is covered with a high quality silk-velvet, closely woven, with an even warp and woof containing no coarse threads, and with short but full-bodied nap. The polishing compound should be a good grade of powdered magnesium oxide reagent. U.S.P. *heavy* magnesium oxide has been found superior to other grades. In the last operations, distilled water must be used exclusively, as the average tap water will not only enhance the formation of hard carbonate particles but will cause the specimen to "fog up" when it is finally removed from the wheel. A small amount of the oxide is placed on the velvet cloth with some distilled water and worked into the nap with the fingers. With the wheel revolving at about 150 r.p.m., the specimen should be held with considerable pressure on the cloth and slowly rotated several times counter to the motion of the wheel. The wheel is then slowed to about 100 r.p.m. and the pressure on the specimen decidedly decreased. Rotating the specimen slowly and under light pressure against the motion of the wheel for about one or two minutes should complete the final polishing. The wheel is then flooded with distilled water to wash the remaining polishing compound from the cloth and from the specimen and the pressure on the specimen is slightly increased for several seconds to complete the cleaning. The piece should then be quickly plunged into hot distilled water, immediately removed, and dried by sharply blowing on it. This method of drying has been found superior to rinsing in alcohol and drying in a warm air blast.

Magnesium oxide is preferred as the polishing medium on the velvet wheel because it is easily obtainable in a texture and quality that permits its direct use in the powdered form and eliminates the time consuming levigations or other refining and grading practices ordinarily required by other fine polishing abrasives. The objection to magnesium oxide lies in its tendency, under some conditions, to form hard particles of the carbonate. This tendency can be mitigated by keeping the powder dry until it is applied to the wheel, or by adding 50% glycerine to the distilled water used on the wheel. In the event that the cloth holding some magnesia is not used for a period of time and a few carbonate particles form, they may be effectively removed by boiling the cloth for several minutes in a 2% solution of hydrochloric acid, which will not affect the cloth.

After the polishing has been completed and the specimen blown dry, it is ready for examination under the microscope or for etching, as the case may be. Examination prior to etching is recommended when looking for cracks, porosity or other defects of a mechanical nature.

Etching of Magnesium Alloys for Metallographic Examination

By R. W. James*

General—Magnesium metallographic samples are usually etched to remove surface flow and reveal the true microstructure. Etching also outlines, attacks or colors the constituents in such manners as to aid in their identification.

Etching Reagents—A number of etching solutions have been recommended by various investigators who have worked with magnesium alloys. Many of the reagents and their specific applications have been reviewed in papers by Gann¹ and by Pulsifer². At present practically all metallographic etching in these laboratories is done with a preparation known as the "glycol etch." Its composition is as follows:

Diethylene glycol.....	75%	by volume
Distilled water	24%	" "
Concentrated nitric acid.....	1%	" "

The glycol etch permits a positive identification and separation of the constituents without severely attacking either the constituents or the matrix.

Some workers with magnesium prefer organic acid etches for grain boundary delineation in wrought alloys. Two of the suggested compositions are as follows:

For wrought magnesium-manganese alloys	For wrought magnesium-aluminum alloys
5 g. citric acid	5 g. malic acid (inactive)
95 cc. distilled water	2 cc. nitric acid (conc.)
	93 cc. ethyl alcohol

Etching Procedure—Pour a small quantity of the glycol solution into a beaker cover (watch glass). Holding the specimen upside down, either with the fingers or with tongs, immerse the polished face with a sliding motion. Do not drop it vertically into the solution. Do not allow the specimen to scrape the bottom of the beaker cover. After the surface is thoroughly wetted by moving the specimen back and forth several times, remove the specimen, turn it over, and blow lightly on the polished face to remove any gas bubbles that may form. An etching time of from 10-15 sec. is recommended for the average sample. Frequently the etching time can be correctly determined by watching the action on the specimen. As much as 30 sec. may be required to reveal completely the grain structure or coring effects in some specimens. When the desired action has taken place the balance of the etchant is removed by plunging the specimen either into a stream of hot water, or preferably, into a beaker of boiling distilled water. It is then dried by blowing sharply on the polished face.

It is suggested that the organic acid etchants, for grain boundary definition in wrought alloys, be applied by swabbing the specimen with absorbent cotton to prevent the etching product from depositing on the sample and obscuring the microstructure. Samples etched with the citric acid solution may be dried as described above. Those etched with the malic acid solution should be rinsed in warm water, immersed in acetone and dried in a warm air blast.

Identification of Constituents—It is recommended that an Eastman No. 78A filter, or its equivalent, be used on the microscope to convert the light to approximately daylight quality. The filter should be used with all arc and filament types of light source. The blue tint obtained aids materially in the separation and identification of the constituents.

Aluminum—Almost all commercial magnesium alloys contain aluminum as the principal alloying element. The magnesium-aluminum phase (the composition of which is somewhat controversial) in its primary condition occurs as a massive white material differing little in appearance from the matrix. The glycol etch sharply outlines the phase and reveals a definite relief as indicated in Fig. 1. The same phase when precipitated from solid solution possesses a lamellar structure quite

*Aluminum Research Laboratories, Cleveland.

similar in its appearance to pearlite of the iron-carbon system. A typical manifestation of the precipitate is shown in Fig. 1 and 4.

Zinc—The magnesium-zinc phase is similar in appearance and etching characteristics to the magnesium-aluminum phase. Practically all zinc-bearing commercial alloys also contain aluminum. In these alloys the aluminum and zinc combine with the magnesium to form a ternary magnesium-aluminum-zinc phase having essentially the same microscopic appearance as the binary magnesium-aluminum- and magnesium-zinc phases. Hence in commercial alloys the magnesium-aluminum-zinc complex will appear as the massive white constituent illustrated in Fig. 2. The micrograph also shows the lamellar precipitated phase of the ternary complex.

Manganese—All commercial magnesium alloys contain some manganese. The manganese constituent is generally spheroidal, has a pronounced relief and possesses a slate gray color. It is practically unaffected by the glycol etch, but is easily recognized because of its characteristic occurrence. Typical particles of this constituent are shown in Fig. 3.

Silicon—Silicon combines with magnesium to form magnesium silicide to the extent of the available silicon. If the silicon content is fairly high (1.0%) the compound usually develops the characteristic "Chinese script" formation illustrated in Fig. 4. With lower silicon concentrations the compound may occur as massive particles. The magnesium silicide is readily recognized by a powder blue to iridescent blue-green coloration which seems to be intensified somewhat by the glycol etch.

Tin—If the tin concentration is fairly high (6%) the magnesium-tin intermediate phase appears as shown in Fig. 5. It is colored either tan to brown or a dark blue by the glycol etch, the type of coloration depending on the length of time the specimen is etched. The etch clearly reveals coring effects in the as-cast alloy. If the tin concentration is lower than 6% and if aluminum is present the microstructure appears as illustrated in Fig. 6. The light colored constituent is the magnesium-aluminum phase. The dark particle is the magnesium-tin phase which possesses the etching characteristics described above. If the phase is massive there may be some color gradation in the individual particles.

Cadmium—At present there is only one domestic magnesium alloy containing cadmium. Under normal casting conditions the 3.5% cadmium in this alloy is retained entirely in solid solution, hence is not visible in the microstructure.

Conclusion—The micrographs represent the constituents and phases as they occur in as-cast alloys. The microstructures of some magnesium alloys will, of course, be considerably altered by thermal treatments but the etching characteristics of the constituents remaining in the microstructure will not be affected. Hot and cold working operations on magnesium and its alloys produce microstructural changes similar to those produced in other metals by comparable treatments. Mechanical working may refine the structures but will not obscure the identity of the constituents.

Magnesium Alloy Die Castings

By W. H. Gross*

Introduction—The advantages of magnesium alloy die castings are light weight, good mechanical properties, and excellent casting characteristics. Portable tools, typewriters, cameras, optical instruments, vacuum cleaners, goggles, motor rotors and parts, conveyors, recording instruments, and paint spraying equipment are a few of the applications.

The "well and plunger" type die casting machine is generally used. With this machine it is possible to obtain pressures of 5,000 psi., or even higher, resulting in castings of good strength and soundness.

Design—In many cases, dies designed for aluminum may be used for the production of magnesium alloy die castings, needing only to be adapted to the die casting machine. It is often desirable, however, to round off sharp corners and to increase fillets where these were too small in the original design.

The size of magnesium alloy die castings appears to be limited only by the size of the die casting equipment. At the present time, castings weighing 3 lb. and having a projected area of 200 sq. in. are in regular production. A conveyor part approximately 74 in. long has been die cast from magnesium alloy.

In general, the following tolerance limits apply. Closer tolerances may be possible in certain cases, depending upon the die design and the requirements of the user.

Variation from drawing dimension per in. length of solid die.....	0.0015 in.
Minimum tolerance limit within solid die.....	±0.003 in.
Minimum tolerance limit across parting line of die.....	±0.005 in.
Minimum wall thickness of casting.....	0.050 in.

Thicknesses greater than the 0.050 in. minimum above should not be less than A/1000 where A is the surface area in sq. in.

Minimum diameter of cored holes.....	0.062 in.
Maximum depth of cored holes.....	3 times diameter of hole
Draft of side walls per in. of length.....	0.010 in.
(Holes ¼ in. or less in diameter and less than ½ in. in depth will require no draft.)	

Alloys—Special alloys are used where certain property requirements or casting characteristics, not obtainable in the standard alloys, are desired. Table I gives the composition and mechanical properties of the magnesium alloys in regular use.

Table I
Mechanical Properties, Composition, and Characteristics of Magnesium Die Casting Alloys

Al	Composition, %			Tensile Strength, psi.	Yield Strength, psi.	Elong. in 2 in., %	Brinell Hardness	Impact Izod, Ft.-Lb.
	Mg, Balance	Mn	Si					
10.0	0.13	0.5	..	30,000	23,000	1	62	1
9.0	0.13	0.3	0.6	33,000	21,000	3	60	2
		max.						
8.0	0.15	0.3	..	32,000	20,000	3	60	2
6.0	0.2	0.2	..	27,000	17,000	4	50	3

Yield strength is defined as the stress at which the stress-strain curve deviates 0.2% from the modulus line.

Mechanical properties are obtained on standard A.S.T.M. die cast specimens.

Machining—Silicon carbide bakelite process discs have been found excellent where grinding is indicated since they cut well and do not load up. When finer grinding is required, instructions are given below under polishing and buffing.

One advantage of the die casting process is the ability to cast parts to relatively close dimensions, hence little machining is ordinarily required on die castings. When machining operations of any nature are necessary, complete instructions can be found in the article "Machining Magnesium," page 1601.

Finishing—Polishing and Buffing—Magnesium alloy die castings can be readily polished and buffed by the following procedures:

*The Dow Chemical Company, Midland, Mich.

Operation No.	Name	Abrasive	Wheel	Wheel Diameter, In.	R.p.m.
1	Polishing	No. 180 Emery	Glued felt, grease stick or dry	10-14	1800-2000
2	Buffing	No. 67 Tripoli	Unbleached sewed muslin buffs, 64-68 count	10-14	2000-2400
3	Coloring	Dry lime (Vienna) or No. 3 Crocus	Unbleached loose muslin buffs	10-14	2400-2700

Cleaning—After polishing or buffing and before further operations, magnesium alloy die castings should be cleaned according to the instructions given in the article, "Corrosion, Surface Treatment and Protection of Magnesium Alloys," on page 1611.

Chemical Treatment—Magnesium alloy die castings can be chemically treated to produce attractively colored decorative finishes or to provide a base for paint.

Colored finishes are produced on magnesium alloy die castings by treating the casting in a dilute solution of sodium hydroxide containing an organic dye. This operation is carried out in an autoclave at a temperature of approximately 390°F., which is obtained at a pressure of about 225 psi. By this process a great variety of durable colored finishes are obtainable. The luster of the finish is dependent upon the luster of the original casting. Sandblasting provides the only satisfactory surface for colored castings. If protection and not appearance is of prime importance, any mechanical cleaning will suffice.

The chrome-alum treatment provides magnesium alloy die castings with a black decorative finish, which also can be used as a base for paint for outdoor service. This treatment is applied by immersing the cleaned parts in a boiling solution of the following composition, until a black coating is obtained, usually about 10 min.:

Potassium chrome-alum ($K_2Cr_2(SO_4)_4 \cdot 24H_2O$)	4.0 oz.
Sodium dichromate ($Na_2Cr_2O_7 \cdot 2H_2O$)	13.3 oz.
Water	to make 1.0 gal.

Upon removal from the bath the parts should be rinsed thoroughly in fresh water followed by a hot water rinse to facilitate drying.

Properly applied coatings are smooth black and adherent, and are more easily secured on machined, sanded, or wire brushed surfaces. Loosely adherent brown powdery coatings result from depleted solutions which may be revived by small additions of sulphuric acid to maintain the pH of the solution between 3.5 and 2.5. Loose powder may be removed from the castings by wiping or by tumbling in sawdust.

The best base for subsequent paint coatings is obtained by the chrome-pickle treatment described in this Handbook in the article, "Corrosion, Surface Treatment and Painting of Magnesium Alloys," on page 1611. When treating die castings, the solution should be heated to 150°F. The time of treatment should be limited to approximately 5 sec., as a longer time results in the formation of a loose powdery deposit on the surface.

Enamels, Japans, and Lacquers—Before any organic finishing materials are applied to a magnesium die casting it must first be cleaned and chrome-pickled or otherwise treated as described above.

Baking finishes of the enamel and Japan types are ideal for use on magnesium alloy die castings. Speed of finishing, excellent adhesion, imperviousness to moisture, and wear resistance are some of the advantages of baked systems. The use of a primer is strongly recommended for all magnesium alloys. Under baking type materials, Naval Aircraft Factory iron oxide, zinc chromate primer P-23 baked 1 hr. at 250-300°F. has proved satisfactory.

Lacquer type materials have been used on magnesium alloy die castings, but they generally lack the adhesion and toughness found in baked systems. A baked primer or Naval Aircraft Factory zinc chromate primer P-27 can be used under lacquers.

The so-called novelty finishes provide a means of securing a number of unusual and attractive effects for the decorative finishing of magnesium alloy die castings. Through the use of these finishes crystal, crackle, granite, hammered metal, leather, marble, metal luster, mother-of-pearl, wood grain, wrinkle, and other interesting patterns are obtainable. The same baking or air drying primers described earlier can be used under the novelty finishes.

Hot and Cold Working of Magnesium and Its Alloys

By H. Menking*

General—Magnesium alloys harden rapidly with any type of cold work and therefore lend themselves to only small amounts of cold forming. At elevated temperatures, however, most magnesium alloys may be formed into intricate shapes without any trouble. Slow forming produces better results than rapid deformation.

Heating Methods—Equipment—With a few exceptions as indicated below, the proper working temperature is about 550-600°F. For moderate forming operations, temperatures down to 400°F. may be employed. The heating can be accomplished in several ways. The most simple is with a blow torch. While this method requires some control to avoid overheating the work, a little experience will soon enable the operator to handle the blow torch economically and safely to obtain satisfactory results. Heating to temperatures above 750°F. will only slightly lower the mechanical properties of the alloys, but above 800°F. the strength of the alloys is more seriously affected.

Other methods which require small initial investment but are considerably more economical in operation consist of preheating the part to be formed in an oven which may be gas, oil or electrically heated, or for temperatures up to about 530°F. by submerging it in an oil bath of 600W and holding for a few minutes prior to working. The working may also be done in a stream of hot air generated by gas or electric heating. The rapid rate of cooling of light gage magnesium sheet requires speedy handling after the sheet has reached the proper working temperature. Devices which keep the magnesium alloy hot during working, such as heated dies or hot air currents, are therefore often employed. With any method of heating, a blow torch should always be at hand to reheat the work when necessary. The type of heating to be selected in each particular case will largely depend on the operation to be performed and on shop conditions.

Temperature Control—There are several simple ways of controlling the temperature of the magnesium part and ensuring that it is within the proper working range: (1) An electric two-point contact pyrometer will ensure the quickest and most accurate temperature control and is recommended wherever possible. (2) A mark made with blue carpenter's chalk will turn white or light brown at the proper temperature. The chalk mark itself should not be exposed to the flame. (3) The application of a drop of 600W oil to the surface. The flash point will indicate the proper temperature. (4) A skilled operator will be able to judge the proper temperature, approximately, by the sound of the sheet when hammered. At the proper working temperature the sheet emits a dull or wooden sound which becomes more metallic as the sheet cools. (5) Ordinary newspaper formed into a ball and pressed for a moment against the magnesium part will turn to various shades from light yellow to dark brown depending on the temperature. A scale of different shades may readily be made up for comparison purposes.

Blanking and Shearing—In blanking or punching magnesium sheet or flat and thin extruded bar, the clearance between the die and the punching tool should, contrary to aluminum practice, be made as small as the accuracy of the stroke will permit without scoring. A clearance of about 0.015 in. (difference between the dia. of the punch and the die) or less, is recommended. The smoothness of the sheared surfaces increases with decreasing clearance. For good results in blanking and punching, the equipment must therefore be accurate enough to permit close clearances between tool and die. The use of hold-down pressures is recommended.

Heating to 500-600°F. will improve the finish of the sheared surface, and is especially recommended for sheet thicknesses above 0.060 in. and when using tool clearances larger than those recommended above. Allowance in the dimensional layout should be made for the expansion of the magnesium stock during heating. An additional means of improving the sheared surface is a slight rake (about 3°) on the punching tool. Fig. 1 illustrates the recommended practice.

In those cases where punching tools with large clearance are used and the stock is not warmed up for punching, the resulting rough surface must be dressed off to avoid conditions which may lead to failure in service. Rivet holes should be drilled rather than punched.

Mechanical shear blades should have square edges and as little clearance as possible. When hand shearing magnesium sheet, the sheer blade should not be

*American Magnesium Corp., Cleveland.

completely closed after each cut as this may lead to small lateral cracks in the sheet at the end of each cut. For heavier gages, sawing the sheet is often preferable to shearing because of the better surface obtained.

Sheet-Bending—The minimum cold bending radius to which sheets may be subjected varies with the alloy, temper, thickness, and rate of deformation. Type of bending equipment and relation of the axis of the bend to the direction of sheet rolling also exert some influence on the results. Because of these factors the only

Fig. 1—Punching tool for magnesium sheet and plate

Fig. 2—Minimum hot bending radius for 90° and 180° bends.

safe criterion is to determine by actual trial the radius which is required or possible under the conditions of fabrication. Results of laboratory experiments under ideal conditions and recommended shop practice are given in the following table for sheet thicknesses of 0.040-0.060 in.:

Alloy	Minimum Cold Bending Radius for 180° Bends (In Terms of Sheet Thickness <i>t</i>)	
	Laboratory Determinations	Shop Practice
Pure Magnesium (hard).....	5 <i>t</i>	8 <i>t</i>
Pure Magnesium (soft).....	3 <i>t</i>	4 <i>t</i>
1.5% Mn Alloy (hard).....	5 <i>t</i>	8 <i>t</i>
1.5% Mn Alloy (soft).....	3 <i>t</i>	4 <i>t</i>
4% Al-0.4% Mn Alloy (hard)	5 <i>t</i>	8 <i>t</i>
4% Al-0.4% Mn Alloy (soft)	4 <i>t</i>	6 <i>t</i>
6% Al-0.3% Mn Alloy (hard)	5 <i>t</i>	9 <i>t</i>
6% Al-0.3% Mn Alloy (soft) ..	5 <i>t</i>	7 <i>t</i>

The radii in the first column were obtained in laboratory tests with relatively small pieces but experience has shown that it is difficult to duplicate these ideal conditions in actual shop practice. For sheet of less than 0.040 in. thickness smaller radii can be obtained, while larger radii will be required for sheet heavier than 0.060 in. A slight spring-back of the sheet must be taken into account when cold bending.

In hot bending, radii of about 2-2½ times the sheet thickness can be obtained in shop practice regardless of alloy or temper (see Fig. 2). For bending wide pieces of sheet in a brake, preheating in an oven is recommended as blow torch heating may result in an uneven distribution of the heat and lead to warping. Fair results are also obtained by clamping heated steel bars on both sides of the section to be bent. The steel bars will warm the magnesium sheet up sufficiently to permit bending. In either hot or cold bending a slow rate of deformation will give best results. Fig. 3 illustrates the proper way of bending short pieces of sheet by hand in the vise. The lining with round edges will prevent cracking of the sheet at the edge of the vise jaws.

Fig. 3—Chucking in vise for bending small pieces of sheet.

alloy disc of 0.050 in. thickness and 20 in. dia. may be cold domed about 1 in. while a disc of the same dimensions in alloy 4% aluminum-0.4% manganese, will cold dome to about ½ in. However, in most cases the forming should be done hot, using one of the methods which follow:

(1) **Hand Forming Without Dies**—A simple method of hot forming consists of tightly clamping the edges of the sheet which is otherwise unsupported, and

Forming—A slight amount of forming, such as stretching or shrinking, may be done cold. For instance, a 1.5% manganese

hammering it into the desired shape with wooden, rawhide or rubber composition hammers. By frequent reheating with a torch, the sheet is kept in the working temperature range. For small work, a leather pillow, loosely filled with sand, may be used to support the sheet. The sand will give under the hammer blows and the deformation will be less severe. Wooden jigs are used to control the dimensions of the piece as the forming progresses.

(2) **Wooden Dies**—For more accurate work and greater economy, wooden dies can be used, provided the number of pieces to be formed is small. Wooden dies char at the temperature of working and are not suitable for quantity production. Concave dies are used for work of small size while convex dies are preferred for larger work. Often a combination of a convex die with a backing block is suitable, the latter being pressed down upon the work by means of a press or jack.

(3) **Aluminum or Magnesium Dies**—Slightly more expensive but more efficient and durable are aluminum or magnesium dies. Such dies are either made from a casting or a heavy plate. The latter has the advantage of a smoother surface while

a casting must be ground off smoothly before it can be used. Hot aluminum or magnesium dies preserve the heat better than wooden dies and avoid frequent reheating of the magnesium sheet. Magnesium dies do not hold the heat as long as aluminum dies do but are easier to handle due to their lighter weight. A burner may be arranged to keep the aluminum die at the proper working temperature. When using hot dies, it is frequently unnecessary to preheat the magnesium sheet as sufficient heat is imparted by the dies. Lubrication of the die surface is recommended. The actual forming is done with wooden hammers or hammers of soft materials as mentioned under (1). Fig. 4 illustrates this method.

Fig. 4—Die forming of a disc of magnesium alloy sheet. 1. Magnesium alloy sheet. 2. Die (aluminum or magnesium). 3. Backing block (aluminum or magnesium).

presses are most suitable. Lubricated and heated dies are essential factors in this type of forming and the rate of deformation should be as slow as possible. Single or double action presses can be used for light draws. For more severe forming, hydraulic presses are preferred, although single or double action presses may also be used with reduced speed. Often the drawing is done in two or more steps, requiring the corresponding number of dies. In this type of work, the proper temperature for the 4% aluminum-0.4% manganese alloy is approximately 450°F. with a range from 300-600°F. For the 1.5% manganese alloy, a temperature of about 600°F. is recommended.

Drawing of Sheet Profiles—Flat strips of magnesium sheet may be drawn into profiled shapes. This method of producing profiled shapes is used for wall thicknesses below approximately 0.060 in. which cannot easily be obtained by extrusion. The strip is preheated in an oil bath and then drawn through two dies, the first serving to produce a shape approaching the desired profile while the second die produces the final shape. The oil bath serves as heating element and lubricant. The dies are made from magnesium extruded bar, which reduces the die costs. An example of the drawing steps involved is shown in Fig. 5.

Spinning—Magnesium alloy sheet is suitable for spinning if the work is kept hot while it is mounted in the spinning lathe. Only small amounts of spinning may be done cold. The heat is applied by a blow torch and the temperature should be about 400-600°F. Ordinary laundry soap will ensure fairly satisfactory lubrication but the mixture of mutton tallow and paraffine wax described below is preferred. At the proper temperature, the lubricant film will assume a dark brown glossy appearance. Care should be taken to avoid overheating the sheet although this danger is not great due to the rapid rotation of the work. Depending on the severity of the deformation, an r.p.m. of 300-450 is recommended in spinning discs of 15-25 in. dia. The edge of the sheet should be filed clean before starting to reduce

Fig. 5—Drawing of sheet profiles. a. Sheet strip. b. Intermediate shape. c. Final shape.

the risk of edge cracks. Wooden chucks are suitable for a few pieces, but cast aluminum or magnesium chucks are more durable at the temperatures involved and are recommended when spinning fair quantities. Fig. 6 shows spinning samples of 0.051 in. 4% aluminum-0.4% manganese soft sheet.

Bead Rolling—Beads may be rolled into magnesium sheet if the latter is heated. A simple way is to preheat the sheet with a blow torch or preferably in an oven and arrange a blow torch in front of the bead rolls in such a way that, before reaching the rolls, the sheet is heated to the proper temperature. Unless the beads are very shallow they should be rolled in several passes. Liberal radii, slight lubrication, and a slow rate of deformation should be used.

Fig. 6—Spinning of a cup shaped part of 13 in. dia. from 0.051 in. thick sheet.

jected to bending and forming operations to the same extent as the original sheet.

Extruded Shapes—Minimum Bending Radius—Extruded shapes must be heated for bending, unless the bending radius is comparatively large. In view of the wide variations in section and alloy, only general recommendations can be made. The approximate rating of the different alloys as to bending properties is given in the following table in which the group 1 designates the best bending characteristics:

1. Pure Mg, 1.5% Mn Alloy, 4% Al-0.4% Mn Alloy, 3% Al-1% Zn-0.4% Mn Alloy.
2. 3% Al-3% Zn-0.3% Mn Alloy, 6.5% Al-0.75% Zn-0.3% Mn Alloy, 6.5% Al-1.25% Zn-0.3% Mn Alloy.
3. 8.5% Al-0.5% Zn-0.2% Mn Alloy, 10% Al-0.2% Mn Alloy.

Alloys of group 3 take only a small amount of cold bending, and heating reduces their elongation to 2-3%.

A minimum cold bending radius (180° bends) of about 8-10 times the thickness may be used as a guide for $\frac{1}{4}$ in. thick flat extruded bar in the 4% aluminum-0.4% manganese alloy, and 10-15 times for the 6.5% aluminum-0.75% zinc-0.3% manganese alloy. More intricate shapes, such as Tees, require larger cold bending radii.

The minimum hot bending radius (180° bends) for $\frac{1}{4}$ in. thick flat extruded 4% aluminum-0.4% manganese bar is about twice the thickness. For more intricate sections, the minimum hot bending radius should be determined by actual trial.

Bending Equipment—Ordinary profiled steel bending rolls may be used for cold bending extruded shapes. Commercial tube bending machines equipped with proper tools to bend shapes are also suitable. A lubricant is used with the latter. For hot bending, these methods may also be employed, using heated tools. The use of aluminum or preferably magnesium alloy tools will allow rapid heating. When bending rolls or tube bending equipment are not available, either of the following two methods, requiring only inexpensive equipment, may be used:

Fig. 7—Bending of channel section.
1. Die (wood, aluminum, or magnesium).
2. Channel section to be bent. 3. Back-up block. 4. Clamp.

(1) **Cast aluminum or magnesium blocks, heated to about 600°F.**—Fig. 7 shows the blocks used for a channel section. In the case of Tee and similar sections, the block (1) may be split to facilitate removing the web from the slot in the block. The magnesium section is clamped down tightly at one end and then gradually hammered down into the slot by means of a wooden hammer. If wrinkles develop, they are straightened out by hammering after completing the bend. Wooden blocks are suitable for making up a small number of samples, but not for larger quantities as the torch flame will gradually char the wood.

(2) **Profiled Rolls**—A magnesium shape may be bent around a stationary profiled roll of the desired bending diameter, the bending being accomplished by slowly rotating a small roll along the periphery of the big roll from position A to B, as shown in Fig. 8. A flat shape $\frac{1}{4}$ in. x $1\frac{1}{2}$ in. may thus be bent over its narrow side around an 8 in. radius.

Tubing—Magnesium alloy tubing is readily bent on commercial tube bending machines. Cold bending is possible with thin walls and ample radii. More severe bending is done at temperatures from 500-700°F. The tube is filled with fine dry sand to prevent it from flattening. When hot bending, the sand is preheated with the tube and serves to preserve the heat. Steel balls of the exact inside diameter, strung on a cable and inserted into the section to be bent, can also be used to prevent flattening. If a tube bending machine is not available, wooden or cast light metal blocks such as those described for bending extruded shapes, may be used. A small wooden block fitting the outside of the bent tube should be employed as an intermediary tool between the tubing and the hammer used for the bending. Magnesium alloy tubing may be shouldered by spinning. The proper temperature varies from 300-450°F. The recommended r.p.m. of the spinning lathe is from 200-400. Soap is used as lubricant.

Fig. 8—Roll for bending extruded shapes
1. Shape to be bent. 2. Stationary roll. 3. Rotating roll.

Lubricants—C-Metal oil is used for light draws which are performed cold. For difficult draws which are done at elevated temperatures, lard oil or 600W oil is recommended. A mixture of two part of rendered mutton tallow and one part of paraffine wax may also be used. This mixture is prepared by melting, pouring into bricks and rubbing against the blank before drawing.

Machining of Magnesium and Its Alloys

By H. Menking*

Tools—Machining tools of standard design as used for other metals may, in most cases, be employed for magnesium. For maximum economy, however, these tools should be of slightly different design. The main factors governing the design of tools for cutting magnesium are (1) the extremely low cutting resistance, (2) the comparatively low heat capacity of the metal, and (3) the large volume of the chips obtained due to the easy cutting. The low cutting resistance leads to high speeds and heavy feeds and the problem is to dispose of the chips quickly and smoothly without jamming and subsequent development of frictional heat. The low heat capacity tends to create higher temperatures in work, chip and tool under conditions of friction as compared with other metals. These basic factors lead to tools with the following principal characteristics: (1) Smooth tool faces. (2) Large peripheral clearances. (3) Large chip spaces and (in milling cutters) small number of blades. (4) Small areas of the tool in contact with the work. (5) Comparatively small rake angles (undercuts).

In grinding the tools, it is most essential to keep the cutting edge as keen and smooth as possible and free from grinding wheel scratches, burrs or wire edges. In addition, the tools should be kept as smooth as possible wherever they come in contact with the chips in order to facilitate chip flow. Keen tool edges and smooth tool surfaces are best obtained by finish grinding on a fine or very fine abrasive wheel followed by a careful hand stoning with a fine or extra fine oil stone. Tools pre-

Fig. 1—Lathe tool for roughing

Fig. 2—Lathe tool for parting.

viously used for other metals should always be resharpened before cutting magnesium regardless of whether the cutting angles are changed or not.

Tools tipped with tungsten carbide give considerably better results than high carbon or high speed steel tools. They are recommended for maximum efficiency especially in cases where extremely high cutting speeds are employed. The higher price of these tools is more than offset by their longer life, greater accuracy and greater operating economy due to less frequent resharpenings.

Turning—Fig. 1 shows a recommended lathe tool for rough cutting. The large clearance (8-10°) and the small top rake (15-20°) are important. A larger top rake will often cause feeding of the tool into the work. In some machine shops, no top rake is used, which assists in breaking up the chips and prevents curling. Such a tool, however, is not generally recommended since it slightly reduces the smoothness of the machined surface and tends to increase the power consumption. The side rake may vary from 0 to about 10°.

The recommended finishing tool differs from the roughing tool by having a round nose (.040 in. dia.) on the tool tip, producing a smoother finish to the surface. As compared with aluminum it has been general experience that narrower tool noses are sufficient to obtain the same degree of smoothness.

Form tools (broad nose tools) for taking wider cuts or turning specially shaped contours should be designed along the same lines, except that the top rake should

*American Magnesium Corp., Cleveland.

be reduced to about $3-8^\circ$ to avoid chattering. Fig. 2 illustrates a parting tool. The large clearance angles are important to reduce friction and to avoid breakage of the tool.

Planing and Shaping—In principle, the same cutting angles are used as for lathe tools.

Milling—Milling cutters for magnesium should be of the coarse tooth type. They should have considerably less, preferably only one half or one third, as many teeth as is standard with conventional cutters used for iron and other metals. The

Fig. 3—Face Mill.

Fig. 4—Staggered tooth cutter—recommended design of tooth.

larger chip space and the heavier cut resulting from the smaller number of teeth lead to a reduction of frictional heat and to greater chip clearance and consequently to higher speeds, decreased tendency to distortion, lower power consumption and smoother finish. Unless otherwise stated, a primary peripheral clearance of 10° , $\frac{1}{16}$ in. wide, followed by a secondary clearance of 20° is common to all cutters illustrated.

Solid Cutters—Fig. 3 shows a recommended type of face cutter. Fig. 4 illustrates a 6 in. dia. staggered tooth (slotting) cutter with 12 teeth. A helix angle of 15° , an undercut of 20° and an 8° clearance on the side of the tooth are suggested for the latter type of cutter. Plain mills (Fig. 5) are recommended with 25° undercut and 45° helix angle. On form cutters (Fig. 6) the undercut is reduced to $5-8^\circ$ due to the heavier cutting pressure. A larger undercut may result in chattering.

Fig. 5—Plain mill.

Inserted Blade Cutters are less expensive than solid cutters of large diameters and offer a better chance to obtain large chip space. They are therefore used for high peripheral speeds. Fig. 7 shows the design of an 8 in. dia. inserted blade face mill with 6 to 8 blades. The blade design of an 18 in. dia. cutter as used for extremely

Fig. 6—Form cutter.

Fig. 7—Inserted blade face mill—recommended design of blade.

high cutting speeds (5,000 ft. per min.) is shown in Fig. 8-9. Particular attention is called to the unusually small number of blades, the free unobstructed chip space between cutter body and work, the curved out and polished face of the blade and

Fig. 8—Inserted blade face mill for extremely high speeds.

Fig. 9—Design of blade of inserted blade face mill shown in Fig. 8.

the large clearance (16°). All of these features aid chip flow and reduce friction and will therefore make higher cutting speeds possible and increase the life of the teeth.

A suitable type of shell-end cutter is shown in Fig. 10. It is designed along the same lines as the milling cutters described before.

Cutting Speeds and Feeds in Milling and Turning—With the type of machining equipment now used as standard, magnesium alloys may, under ordinary conditions, be machined at maximum spindle speeds and with feeds and cuts up to the capacity of the machines.

Speeds—Peripheral cutting speeds of 5,000 ft. per min. have occasionally been used in milling magnesium alloy castings, taking $\frac{1}{4}$ in. cuts and feeds of 0.045 in. per revolution in roughing, and 0.004 in. cuts and feeds of 0.015 in. per revolution in finishing. While such speeds are still considered exceptional, speeds of 1,000-3,000 ft. per min. in milling and turning magnesium are standard practice in many machine shops. Due to limitations in the spindle speed, such speeds can, in milling, be obtained only with large diameter cutters, or in turning, with castings of large diameter. With a given maximum spindle speed, the diameter of the milling cutter is often enlarged in order to increase the peripheral speed when changing from aluminum to magnesium castings. Magnesium castings are not dynamically unbalanced to the same degree as are parts of a heavier metal. This will tend to reduce the force of possible vibrations and allow higher cutting speeds. Milling cutters with magnesium bodies have been developed for extremely high speeds in order to reduce or eliminate vibration.

Feeds and Cuts—The highest feed that can be attained within the capacity of the available equipment may in most cases be used for roughing. In cases where mechanical feed is too slow, hand feeding is often resorted to in order to increase the machine output. Roughing feeds up to 0.080 in. per revolution have frequently been used. In finishing, where the smoothness of the surface is the controlling factor, a better surface can be obtained with the same feed, and an equally smooth surface with a greater feed when machining magnesium as compared with aluminum alloys. Frequently a special finishing operation is unnecessary due to the smooth finish obtained in roughing. Cuts of $\frac{1}{4}$ in. and more may be taken with the proper tools and with rigid chucking. With a machine of 5 hp. capacity, a cutter of suitable design will take $\frac{1}{4}$ in. cuts with feeds of 15 in. per min. (0.035 in. per revolution) and peripheral cutting speeds of 900 ft. per min. The use of greater feeds actually results in a reduction of frictional heat and in freer cutting. It has been observed at times that the work becomes quite hot and the chips jam the cutter when using low speeds and feeds, whereas free cutting and low temperatures will be obtained when the speed and feed are increased.

Fig. 10—Shell end cutter.

Limiting Factors—The following factors tend to limit the use of high speeds and feeds:

- (1) Dull tools, or ones of incorrect design (too small clearances, insufficient chip space) will cause frictional heat and warping.
- (2) Magnesium alloys will sometimes, due to their lower elastic modulus, require more rigid chucking than aluminum alloys to avoid chattering when maximum speeds are to be used. Where this is impracticable the speed and feed must be reduced.
- (3) The shape and design of the work may limit the cutting speed. If a casting with light and thin sections is machined at high speeds, the spring of the metal and the resulting vibration may result in chattering and inaccurate dimensions. More rigid chucking or reduced speed and feed will help to improve such a condition.
- (4) Fine or light feeds will sometimes generate frictional heat which may result in distortion and inaccuracy of dimensions. In combination with dull or improperly designed tools and high cutting speeds, they may occasionally lead to the ignition of fine shavings. While this condition can be controlled by the use of coolants and lubricants, the general rule should be to avoid extremely light feeds where possible.

Reaming—For reamers for magnesium, a small clearance (3-4°) and a small undercut (5-6°) is recommended in order to secure a steady cut without vibration. A recommended type of solid expansion reamer is shown in Fig. 11. The special steel and diamond boring tools often used for reaming are well suited for magnesium.

Fig. 11—Solid expansion reamer

Drilling—Two different types of twist drills are recommended, depending on the depth of the hole to be drilled.

Deep Holes—A drill for deep holes (more than about four times dia.) should have a spiral angle of about 40°, a parallel web and smoothly polished flutes in order to ensure rapid flowing of the chips. The clearance (relief behind land) should be twice as deep as with standard drills. The land (or margin) should be narrower than customary ($\frac{1}{2}$ of standard width). A point angle of 110-120° and a lip clearance of 15° is recommended. A drill of this design will cut freely and will readily clear out the chips. Raising the drill to remove the chips will be unnecessary unless the hole is deeper than about 15 times the dia. A drill of suitable design is illustrated in Fig. 12.

Fig. 12—Drill for deep holes.

Too close a distance between the drill jig bushing and the surface of the drilled part will prevent the chips from flowing out readily and will cause them to jam in the flutes. An approximate minimum distance of $1\frac{1}{2}$ times the hole diameter is recommended.

Short Holes—The main feature of a drill for short holes (less than about four times dia.) is a small spiral angle, preferably about 10°. Second choice are "Brass Type" drills, with a spiral angle of 25°. Such drills will work satisfactorily for depths up to about 4 times the dia., especially when provided with a flat ground along the cutting edge. This flat will reduce the tendency of the drill to hook into the work and to lift it when the point breaks through the under side. 40° spiral drills show this tendency to an even greater extent. They are satisfactory, however, when the work is firmly clamped. Fig. 13 shows a 10° spiral drill, and Fig. 14 a "Brass Type" drill with flat ground on.

Fig. 13— $\frac{3}{8}$ in. dia. drill for short holes—recommended type.

Fig. 14— $\frac{3}{8}$ in. dia. drill for short holes—permissible type. (Note flat ground along cutting edge.)

Speeds and Feeds in Drilling—Peripheral speeds of about 300 ft. per min. are considered standard practice for magnesium by many machine shops. The feeds should be considerably heavier than those used on other metals, for instance about 0.020-0.040 in. on $\frac{1}{4}$ in. holes.

Counter Boring—A recommended counter boring tool is shown in Fig. 15. An important feature is the narrow cylindrical land which is only about 0.015 in.

Tapping—A suitable tap design is illustrated in Fig. 16. The acute back angle of the land (3-4°) results in cutting rather than squeezing the metal when backing out of the tapped hole. The slightly greater springback of magnesium as compared with other metals makes this precaution advisable. The lands should be shorter than usual and cylindrical, that is, there should be no clearance on the land. This will reduce the possibility of chips getting jammed in the clearance space and building up on the land. Unlike drills, taps for magnesium are usually not made oversize. The resulting tight fit of the stud is desirable for satisfactory service. A thread-length of two to three times the diameter is recommended.

Fig. 15—Counterboring tool

No trouble is encountered with the "seizing" of threaded magnesium parts, when in contact with magnesium, aluminum or any other metal. Steel or brass inserts should be used in cases where the screw bolt or stud is frequently removed.

Grinding—Medium hard grinding wheels of melted clay bond with a grain size varying from 40 (medium coarse) to 80 (medium fine) are satisfactory for most purposes. For rough grinding (snagging), a grain size of about 20 is recommended. In grinding magnesium, a certain fire hazard is involved. The recommendations given below will practically eliminate this hazard and should therefore be carefully followed.

Wet Grinding—A liquid cooling agent, preferably crude oil, should be used whenever possible. The oil vapors developed during grinding should be exhausted. In those cases where exhausting is impracticable, a 3-4% soluble oil solution or a mixture of 10 gal. of water; 3½ pints of crude oil; and 3½ lb. of sodium carbonate should be used. In exceptional cases water may be employed. Any adhering traces of the solution should be removed from the magnesium parts soon after grinding.

Dry Grinding—In cases where the use of a liquid coolant is not practicable, the grinding may be done dry if provision is made for exhausting the grinding dust with sufficiently high suction speed (80-100 ft. per sec.). The grindings should either be precipitated by means of a water spray as soon as possible after leaving the grinding wheel or they may be sucked into an overflow water tank. A part of the grindings will flow into the sewer with the water while the rest settles down to the bottom of the tank and should be removed every two or three weeks. The exhaust pipe system should be equipped with safety valves to safeguard against explosion.

Fig. 16—Angles recommended for taps.

The following additional precautions are suggested:

- (1) Sparking of any kind is to be avoided in the vicinity of equipment on which magnesium is ground.
- (2) Iron or steel must not be ground on wheels used for magnesium nor in their vicinity. Grinding wheels for magnesium should be clearly marked as such.
- (3) An easily removable apron and hat should be worn by the operator. Rubber clothing is particularly recommended because of its smoothness. Anything apt to collect grinding dust on the clothing of the operator should be avoided, such as pockets or a rough clothing surface. Goggles should be used.
- (4) Grindings should not be allowed to accumulate on the clothing of the operator. They should frequently be brushed off or blown off with air.
- (5) The grindings should be frequently removed from the machines and placed in tightly covered iron cans in a location which is safe from sparking and fire. The magnesium content of grindings cannot economically be recovered and should be disposed of in water.
- (6) Before dressing the grinding wheel, the exhaust device should be shut off and all magnesium grinding dust blown off the machine and the wheel.

Polishing—In polishing, sandpaper of a suitable grade should be used. Emery paper will tend to cause sparking and is therefore not recommended. In order to maintain the bright shine of the polished surface, it should be slightly greased with vaseline or an equivalent grease, or painted with a recommended brand of clear lacquer. Polished surfaces not protected in this way will soon tarnish. For larger polishing operations, the same precautions as for grinding are recommended.

Sawing—Magnesium is readily cut by band or circular saws. Sharp blades are essential for satisfactory results. Lubricating with a tallow stick will facilitate the work.

The following is recommended for band saws:

	Thickness of Blade, in.	Width of Blade, in.	Teeth per inch
For smaller work.....	.030—.040	$\frac{1}{8}$ —1	8
For heavier work.....	.045—.050	$1\frac{1}{2}$ —2 $\frac{1}{2}$	5

The set of the teeth should be greater than standard so as to reduce friction. For circular saws, blades of about 10 in. dia. and .040 in. thickness with 5 to 7 teeth to the inch and a set of about .055 in. are satisfactory for cutting sections up to about 2 in. dia. Hack saws should have 14-18 teeth to the inch, every third tooth being a clearance tooth without set. A satisfactory size is .025-.030 in. thickness and $\frac{1}{2}$ in. width.

Filing—For hand work, single or double cut files may be used, although single cut files work better. Files with rasp cut produce too rough a surface. Depending on the smoothness desired, bastard, second cut or smooth files are used. For rotary files, medium coarse single cut files are found best. Too coarse a cut will result in chattering.

Lubricating and Cooling—Due to its great ease of machining and the small amount of frictional heat developed with proper tools, magnesium may be machined dry without difficulty. Arrangements for dry machining should be made wherever possible, with the following exceptions:

(1) *Smooth Finish*—A lubricant may be used in reaming and occasionally in other operations, when the smoothest possible finish is desired. However, a slight change of the tool nose will usually produce the same result without lubricant.

(2) *Distortion*—At times the cutting heat generated in the work cannot be quickly dissipated and the part will distort during or after machining. This condition may be due to the particular shape of the work which may hinder the free flowing away of the heat, or it may be caused by excessive generation of frictional heat as described under "Prevention of Distortion." In those cases where the cause for the slow dissipation of heat cannot be eliminated, distortion may be prevented by cooling both the work and the tool with compressed air, or where this is not considered practicable, with a liquid cooling agent.

(3) *Fire Hazard*—For grinding, a liquid cooling agent should be used to eliminate the fire hazard. The same precaution is often applied in machining magnesium parts with an insert of ferrous metal as sparking sometimes occurs when the tool strikes the insert. Too slow a dissipation of heat as described under (2) may also lead to ignition under certain conditions and calls for the use of air or liquid cooling.

Lubricants or coolants with the lowest percentage of water should be selected, such as kerosene or preferably mixtures of equal parts of kerosene and pure lard oil. Soluble oil solutions (mineral oils) may be used but should be avoided, due to their greater oxidizing effect on the turnings. Vegetable oils are not recommended.

Prevention of Distortion—Occasionally, a slight distortion of magnesium parts is observed during or after machining. This is infrequent and can generally be attributed to the following:

Frictional Heat—This will often result in distortion. Magnesium has a lower specific heat than aluminum and is therefore more liable to heat and warp under friction. Factors (all of which are avoidable) causing frictional heat are:

- (1) Dull tools.
- (2) Tools with cutting angles other than those recommended above.
- (3) Very fine feeds and cuts.
- (4) Insufficient chip space.
- (5) Slow speed. This is liable to cause jamming of chips, especially in combination with small feeds. Fast speeds increase the centrifugal force and throw out the chips, thus reducing the tendency of the chips to jam.

Inadequate Clamping or Chucking—Magnesium alloys have a lower elastic modulus than other alloys, which may, at times, lead to somewhat greater deformation under the cutting pressure if light sections of the work are not rigidly mounted.

Casting or Heat Treating Strains have seldom been found to cause distortion of magnesium castings during machining. Castings with a tendency to such strains can be given a normalizing heat treatment when found necessary. In exceptional cases, however, this treatment is insufficient, and the casting strains are only released by the roughing cut. In such cases, the castings should be allowed to rest for two or three days between the roughing and finishing cut. In addition, they may, if

necessary, be given another normalizing treatment consisting of heating to about 500°F. for two hours and cooling slowly.

Automatic Screw Machine Work—Speeds and Feeds—Magnesium alloy screw machine stock (3-7% aluminum recommended) may be machined at higher speeds and feeds than used for other metals. Due to speed limitations of the machine, however, the maximum economies offered in machining magnesium may not be obtainable in all cases. The possible increase of the feed over other metals will depend on the conditions but a feed of approximately 40% higher than used on brass may be considered an average figure. In general, better results are obtained with heavy feeds than with light ones.

Box Tool—Tool angles recommended for box tools are shown in Fig. 17. A tool ground in this way will produce a satisfactory finish. The angle shown as 10° is to

Fig. 17—Box tool for screw machine work

Fig. 18—Circular forming tool for screw machine work.

be considered an average and may vary within a relatively wide range depending on conditions (about 8 to 15°).

Circular Forming Tool—The circular form tool shown in Fig. 18 is one of the types most commonly used for automatic screw machine work. At "A" the tool is shown without top rake, which is satisfactory for magnesium. Frequently, it is necessary to grind the tool with a few degrees top rake as shown at "B" to correct a slight error in the steps of the tool. Top rake will produce satisfactory results but no rake is preferable as this will give better chip breakage. The side clearance indicated at "C" should not exceed one quarter degree. In most cases best results are obtained when the tool is without side clearance or with a slight negative rake.

The front clearance angle "D" is controlled by the design of machine and tool holder. A standard clearance angle has been determined for each type of machine and is considered satisfactory for all metals. This angle may vary slightly from one machine to another.

When using a side forming tool without support, the ratio of the width of tool to the smallest diameter on the work should not exceed 2:1 for magnesium.

Chips—With light feeds in machining magnesium, the chips form in coils or ribbons. When the feeds are increased, the chips break up and with relatively heavy feeds, they are well broken. The chips produced in machining magnesium do not increase in thickness as they pass across the tool. Their thickness is about equivalent to the advance of the tool, indicating that there is no adherence of the metal.

Cutting Oil—Contrary to ordinary magnesium machining practice, the use of a cutting oil is recommended for magnesium screw machine work. A grade of paraffin oil similar to that used for brass will be satisfactory for machining magnesium. The flash point of this oil should not be less than approximately 300°F.

Machine Shop Scrap—Care should be taken to keep the magnesium scrap free from contamination with other metals, floor sweepings and the like and as far as possible free from oil or moisture. They should be stored during accumulation in tightly covered metal containers. Grindings should be disposed of in water.

Fire Precautions—Ordinarily, the fire hazard in machining magnesium is slight and with a sound knowledge of the correct machining practice, ignition of the shavings may be easily avoided. In order to ignite magnesium, it is first necessary to reach the melting point of the metal. Partial melting begins, depending on the alloy, at temperatures between 800 and 1200°F. In roughing operations, it is very difficult to attain such temperatures, for the high heat conductivity of magnesium rapidly dissipates any frictional heat generated.

In finishing operations, however, where light shavings are necessarily produced, temperatures sufficiently high for ignition may, under certain circumstances, be reached. Factors which will tend to produce such temperatures in the chips or shavings are: (1) Very fine feeds or cuts. (2) Dull or chipped tools. (3) Tools with small clearances and small chip space. (4) High cutting speeds.

A combination of two or three of the above factors may lead to the ignition of the shaving. Sharp tools with ample clearance will greatly reduce the fire risk. Coarser feeds, deeper cuts and lower speeds will act in the same direction but in cases where fine feeds and cuts and highest speeds are essential to quality and economy of work, a liquid coolant should be used.

In turning, ignition may occur if the cutting is interrupted and the feed stopped while the work still revolves. In these cases, the tool should be backed away from the work. In machining magnesium parts with an insert of ferrous metal, sparking sometimes occurs when the tool strikes the insert. In such instances, the use of a lubricant has often been found advisable.

Under no circumstances should water or any other type of standard fire extinguisher, such as pressure or liquid type, be used for extinguishing a fire, as this will make the fire more violent instead of smothering it. Anything that shuts off the air from the burning chips will quickly and effectively smother the fire. The best way is to cover the burning chips with dry asbestos powder or dry cast iron turnings which should be easily accessible. It is recommended that a large container (about 6 cu. ft.) of dry cast iron turnings be placed at each machine. Dry or oil soaked sand is as effective as cast iron turnings but will soil the machine bed. Quick results are often obtained by smothering the fire with an iron plate or an asbestos mat or blanket. The smothering material should be gently applied in order to avoid scattering the fire. Air drafts will also tend to scatter the fire and should be avoided. A good precautionary measure is covering the floor around the machine with cast iron or steel plates.

In its initial stage, a spread of the fire may often be easily avoided by localizing the burning spot and scraping away the adjacent turnings. Care should in general be taken to avoid any accumulation of magnesium chips on, under or around the machine parts for the danger of the spread of the fire will be minimized if the amount of chips on the machine is small. Avoiding any accumulation of chips on the body or clothing of the operator is of particular importance. The chips should be removed at regular intervals and stored in tightly covered metal cans until they can be disposed of. Special fire precautions necessary in grinding are discussed under "Grinding."

Precautions During Machining—1. Do not allow chips or grindings to accumulate on machine or clothing. Store chips in covered metal cans. 2. Place a 6 cu. ft. container with cast iron turnings or dry sand at each machine. 3. Keep cutting tools sharp. Use tools with proper clearances. 4. Take heavy cuts. Back away tool from revolving work when not cutting. 5. Use lubricant when machining magnesium castings with steel or metal inserts or when taking light cuts at high speeds or when using dull or improperly designed tools. In all other cases machine dry. 6. Avoid any sparking. Avoid smoking. 7. Grind with lubricant or water or with dust exhausting equipment with precipitation of the grindings in water. 8. In grinding, a smooth and easily removable apron should be worn by the operator. 9. Do not grind steel or any other metal on wheels on which magnesium is ground. 10. Dispose of grindings under water.

Directions for Extinguishing Fires—1. Localize fire and scrape away adjacent turnings. 2. In initial stage, smother fire with iron plate, asbestos cloth or blanket. 3. Cover the oxidizing chips with one of the following materials: Cast iron turnings, dry sand, graphite, dry earth or asbestos powder. 4. Do not use water or any other type of standard fire extinguisher.

Riveting of Magnesium and Its Alloys

By H. Menking*

Rivet Alloy—Magnesium alloys can be riveted in a satisfactory manner with aluminum alloy rivets. For thin gages of sheet or for slightly stressed parts commercially pure aluminum (2S) rivets are recommended. For heavier gages and for stressed construction, a 5% magnesium (balance aluminum) rivet should be used. This alloy was developed in order to lessen corrosive attack of the magnesium sheet due to electrolytic action between sheet and rivet. Aluminum alloys with different magnesium content may also be used under less severe corrosive conditions.

Steel, copper, brass, bronze or duralumin rivets are not recommended because there is a possibility of electrolytic action in the presence of moisture and insufficient paint protection. Magnesium alloy rivets do not develop electrolytic action in contact with magnesium alloy sheet, but are not satisfactory due to their low shear strength and the necessity of driving them hot even in small sizes. Magnesium alloy rivets are therefore not supplied commercially.

Physical Properties—The 5% magnesium-aluminum alloy rivets are made from annealed wire and are supplied in the "as formed" condition. Typical physical properties of this alloy are as follows: Tensile strength, 41,000 psi.; yield strength, 18,000 psi.; elongation, 33%; Brinell hardness, 71; shear strength of cold driven rivet, 32,000 psi.; pressure required to drive $\frac{1}{8}$ in. buttonhead rivets (cold), 23 tons.

Design and Preparation of Riveted Joints—The rivets should not be placed too close to each other or to the edge of the sheet as this may lead to local over-stressing. A minimum distance of twice the rivet diameter is recommended between rivet and edge of sheet and three times the rivet diameter between rivets. The following rivet diameters are suggested for the lighter gage sheets.

Sheet Thickness, in.	Up to 0.040	0.040-0.060	0.060-0.100	0.080-0.120	0.100-0.140
Dia. of Rivet, in.	$\frac{1}{8}$	$\frac{1}{4}$	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{5}{8}$

The rivet holes should be drilled rather than punched, as punching tends to produce a rough and flaky surface in the hole. If punched, they should be finished with a drill to obtain a smooth surface. Rounding the edges of the hole will reduce edge stresses and fatigue failures. In driving the rivet, care should be taken to avoid damaging the sheet with the riveting hammer. Rivet shanks should fit holes snugly. For rivet dia. from $\frac{1}{8}$ - $\frac{1}{2}$ in. the clearance should be not more than $\frac{1}{32}$ in. and not less than $\frac{1}{64}$ in. Care should be taken to avoid loose joints. The rivet shank should not be too long in proportion to the rivet hole as otherwise high lateral stresses will be exerted on the sheet during driving, which will reduce the strength of the joint and may lead to fatigue cracks or to cracks of the sheet edge under the rivet head during driving. In driving the rivets in the shop, the use of cone point head tools is recommended. Cone point heads, as compared with other types of heads, require less driving pressure and reduce the tendency of the sheet and the rivet head to crack. The pressure required to drive magnesium-aluminum rivets is slightly lower than that required for duralumin (17S) rivets. No heat treatment of any kind is required for the magnesium-aluminum alloy.

The magnesium-aluminum rivets (AM55S) of $\frac{1}{8}$ in. dia. and over are usually driven hot. In this case, the rivets should be preheated in an oven to about 630-670°F.

Corrosion Prevention—In those cases where corrosive conditions are apt to be encountered, and where the rivet is driven cold, it should be dipped into a suitable bitumastic paint prior to placing in the rivet hole in order to prevent electrolytic corrosion. The excess paint will be squeezed out under the rivet head and will form an insulating layer. Although the magnesium-aluminum and commercially pure aluminum alloy rivets have only a slight tendency toward electrolytic action in contact with magnesium sheet, the above procedure will serve as an additional safeguard to prevent corrosion under conditions of ordinary exposure, and should always be used for applications in the presence of salt air or salt spray. The excess of semisolid paint or sealing compound squeezed out from under the rivet head should be removed before painting the riveted structure to prevent its bleeding through the paint. The contacting surfaces of the riveted magnesium sheet or extruded shape should be painted before assembly.

*American Magnesium Corp., Cleveland.

In those cases where the magnesium-aluminum or 2S alloy rivets are not available and duralumin rivets must be used, the above precautions for protection should be followed even more rigidly because of the greater tendency to electrolytic action. In such cases, in addition to the above measures, gaskets or washers are recommended between the rivet head and the magnesium surface to insure the necessary insulation. Suitable gasket materials are: Bakelite; fiber; gasket paper; leather free from chromium salts; hard rubber; heavy paper, treated with shellac, bitumastic paint, a primer in accordance with Navy specification P-27; or Bakelite varnish.

If fiber or commercial gasket paper is used, the particular brand used should be analyzed to make sure that it does not contain chlorides or other salts.

Protection of Magnesium Against Corrosion

By John A. Gann*

General—Magnesium alloys are quite resistant to corrosion under ordinary urban and rural exposure. Under such conditions, the metal gradually dulls and darkens but suffers no loss in mechanical properties. Corrosion may become more pronounced in heavy industrial areas and particularly along the sea coast. This results in a roughening of the surface and even pitting under extreme conditions. The alloys are free from intercrystalline corrosion so that changes in properties due to corrosion can be estimated by the amount of surface attack.

The corrosion resistance of magnesium alloys to many chemicals has been determined in laboratory tests and under actual operating conditions. Inasmuch as the corrosion resistance of any metal is affected not only by the medium to which it is exposed but also by the operating conditions, service tests should always be made before using magnesium alloys for any special applications. Table I indicates the corrosion characteristics of magnesium alloys in contact with a variety of materials.

Table I
Corrosion Characteristics of Magnesium Alloys

Chemical	Concentration ¹	Recommendation ²

²Recommendations are based on the behavior of unprotected metal. In a few cases protective coatings permit the use of magnesium alloys with chemicals that normally corrode them.

R = recommended for use. N = not recommended for use. W = may be satisfactory, but trial under operating conditions is warranted.

Magnesium alloy parts are generally given protective paint coatings because it is difficult to control the location and conditions under which they will be used

*The Dow Chemical Co., Midland, Mich.

Many jobs are painted for decorative purposes. In order to secure maximum protection, it is necessary to follow certain established procedures, discussed below.

Cleaning—Prior to the application of a chemical treatment to magnesium alloys, it is necessary to have the surface free from dust, dirt, oil, and grease. Loosely adherent material should be brushed off. Oxide films and adherent dirt should be removed mechanically, by sand blasting, wire brushing, or grinding; or chemically, by pickling in a 1-10% solution of sulphuric acid. After the acid pickling, the parts should be given a wash in cold running water followed by a hot water (140-180°F.) rinse to facilitate drying.

Oil and grease are removed by washing with an organic solvent such as carbon tetrachloride, gasoline, or naphtha; or by treatment in hot alkaline cleaners. Parts cleaned with organic solvents should receive a final rinse in clean unused solvent. The mild alkaline cleaners developed for aluminum can be used, but faster and more efficient cleaning will be obtained through the use of the stronger alkaline cleaners, as used on steel, or an inexpensive mixture made in accordance with the following formula:

Sodium Carbonate (Soda Ash).....	3 oz.
Sodium Hydroxide (Caustic Soda).....	2 oz.
Soap	1 oz.
Water, to make.....	1 gal.

Magnesium alloys are not attacked by such cleaners, which should be used at boiling temperature. Parts so treated should be given a wash in cold running water, followed by a hot water rinse to facilitate drying.

Chemical Treatment—Magnesium alloy surfaces must be given a chemical treatment prior to painting in order to insure satisfactory results. The application of ordinary paint coats to bare magnesium, regardless of how well it may have been cleaned, will result in unsatisfactory adhesion to the metal. No paint is entirely impervious to moisture; and sooner or later, depending on the conditions of exposure, the paint will begin to lift from untreated metal. This may take place without apparent attack on the underlying metal.

Chrome Pickle Treatment—The chemical treatment generally used is known as the "chrome pickle" or "bichromate coating." It is well bonded to the metal, has a satisfactory mechanical tooth for subsequent paint coatings, and has definite corrosion inhibitive characteristics. This treatment is a simple dip operation requiring ½-2 min., according to the freshness of the bath and cleanliness of the article. The recommended bath has the following composition and is operated at room temperature:

Sodium dichromate ($\text{Na}_2\text{Cr}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$).....	1.5 lb.
Nitric acid (HNO_3 , sp. gr. 1.4).....	1.5 pint
Water, to make.....	1 gal.

Containers for this bath should be made of pure aluminum, glass, or earthenware. After the dip, the parts should be held above the tank for about 5 sec. This serves a double purpose; to allow the adhering solution to drain off, and to produce a better colored and more effective coating. The parts are now washed in cold running water, followed by a hot water rinse which completes the washing and facilitates drying.

The chrome pickle treatment produces a visible color with a matte to bright finish on the article. The color and luster vary with the composition or age of the solution and also with the composition and type of heat treatment of the alloy. Matte, gray to yellow-red, iridescent coatings are best paint bases and are readily obtained in fresh solutions. Bright brassy coatings are to be avoided. They are produced in solutions which contain too much acid, or in solutions which have been revived too many times.

The bath may be operated until the nitric acid content is depleted to 1.0 pint per gal. at which stage the sodium dichromate concentration will be about 1.3 lb. per gal. The solution should then be revived to contain 1.3 to 1.4 pints of nitric acid and 1.5 lb. of sodium dichromate per gal. This reviving operation may be performed 7 or 8 times, whereupon byproducts of the process will have built up in the solution impairing the efficiency to such an extent that the bath should be discarded. A rough control of the bath composition may be conducted on the basis of color of coating, etch produced, and degree of action observed. Exhaustion of the

solution is indicated by the paleness of color and slowness of action on the metal. This paleness in color should not be confused with that caused by insufficient exposure of air between removal from the bath and the wash in water. Nitric acid and sodium dichromate should be added until a matte or semimatte (not bright) coating is produced, remembering that the nitric acid content diminishes more rapidly than the sodium dichromate content.

Articles too large to be immersed should be well brushed with a generous amount of the solution (preferably freshly made), well washed with a brush and water, rinsed, and dried. The coating thus formed is less uniform in color than that produced by the dip process but is equally good as a paint base if sufficient solution is used. If die castings are to be given the chrome pickle treatment, the solution should be heated to 150°F. The time of treatment should be limited to approximately 5 seconds as a longer time results in the formation of a loose powdery deposit on the surface of the casting.

The chrome pickle treatment, as described above, is given in Specification M-303, part 1, Navy Department, Bureau of Aeronautics, and in United States Army Specification No. 98-20010.

Magnesium castings and wrought shapes are normally chrome pickled or bichromated prior to shipment. If this chemical finish is subsequently damaged or removed during forming or machining operations, the parts should be retreated prior to painting. Since the normal treatment removes 0.001-0.002 in. of metal, machined surfaces that must be held to accurate dimensions should be given a shorter time chrome pickle treatment or, as an alternative, the modified alkaline dichromate treatment described below.

Modified Alkaline Dichromate Treatment—This treatment is not intended to replace the chrome pickle treatment, but is recommended as an alternative for those cases in which dimensional changes, as on machined surfaces, are to be kept at a minimum. Parts given the treatment show no dimensional loss. Properly applied the alkaline dichromate treatment provides the magnesium alloy article with a black decorative finish.

Immediately prior to treatment, the parts must be very thoroughly cleaned in accordance with previous instructions, preferably with an alkaline cleaner or by boiling for five minutes in a solution of 2% sodium hydroxide followed by a hot water rinse. Next immerse parts 5 min. in a water solution containing 15 to 20% by weight of hydrofluoric acid (HF) at room temperature. Wash in cold running water and then immerse parts 45 min. in a boiling solution containing:

Ammonium sulphate, $(\text{NH}_4)_2\text{SO}_4$	4 oz.
Sodium dichromate, $\text{Na}_2\text{Cr}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$	4 oz.
Ammonia (sp. gr. 0.880).....	$\frac{7}{8}$ fluid oz.
Water to make.....	1 gal.

The treated parts should be washed immediately in cold running water. As the final step, boil parts 5 min. in a water solution containing 1% by weight of arsenous oxide (As_2O_3). Rinse parts thoroughly in cold running water followed by a dip in hot water to facilitate drying.

In large scale operation the sulphate-dichromate solution may be easily controlled and maintained at proper concentration. The pH value should be held between 5.6 and 6.2 by additions of chromic acid and concentrated sulphuric acid in equal proportions by weight. Aluminum or steel tanks can be used for the solution which can be heated externally with gas or internally with steam coils. A loosely fitted lid can be used to minimize loss by evaporation.

The alkaline dichromate treatment, as described above, is given in Specification M-303, part 3, Navy Department, Bureau of Aeronautics

Dichromate Boil—This treatment is simpler to apply but is just as effective as the modified alkaline dichromate. It is not, however, covered by government specification at this writing.

Clean parts and dip in hydrofluoric acid the same as in the modified alkaline dichromate treatment. Rinse in cold running water and then immerse parts 45 min. in a water solution containing 10% by weight of sodium dichromate ($\text{Na}_2\text{Cr}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$). Wash in cold running water and then dip in hot water to facilitate drying. Control is accomplished by keeping the bath at a pH of 4.2 by additions of chromic acid.

Painting—The successful painting of magnesium offers no unusual difficulties today where approved materials are used and good painting practice is observed. So far as the problem of protection is concerned, the service conditions fall into

three general classes: 1. Interior, such as in the home, office, or factory not employing corrosive chemicals; 2. Exterior, such as inland North American atmospheres; and 3. Seaboard atmospheres containing sea salts or spray, or tropical areas of high humidity.

Primers—Before priming, any grease, oil, or dust must be removed from the chrome pickled surface, preferably by a thorough solvent wipe. Under no circumstances should sanding, phosphate cleaner, or any other treatment designed to roughen the surface be used over the chrome pickle.

Care in the selection of the primer cannot be overstressed, especially in regard to its adhesion and corrosion inhibitive characteristics. Natural adhesion is the most important property for a primer to be used under average indoor and exterior conditions. Zinc chromate primers possess distinct inhibitive properties with fair adhesion and hence should be used where corrosion conditions are severe, such as exposure near salt water or to continuous moist air. In cases where it is difficult to predict the service conditions under which a piece of equipment will be used, it is generally best to employ a chromate primer meeting Navy Specification P-27 or Army Specification 14080.

Surfacers—A sealing or surfacer coat should be used over the primer coat and prior to the application of the finish coats where smoothness is of importance. Such a coat improves the adhesion and wear resistance of the paint job. For conditions of severe exposure, however, an additional finish coat has more protective value than a coat of surfacer.

Finishes—Almost any good quality oil paint can be used over a recommended primer on indoor exposure where wear resistance is not required. Full synthetic and oil-base synthetic enamels, or high grade spar varnish pigmented with aluminum paste, have proved satisfactory for general exterior work. Experience has demonstrated the economy of an additional finish coat, since the added protection is well worth the expense, especially on parts to be used on Naval aircraft. Lacquer type coatings should be used judiciously, since they appear to lack the necessary expansion characteristics. They may be useful, however, for certain interior applications. Clear coatings have only a limited application on magnesium. They are sometimes desirable for indoor service in order to preserve the natural metallic luster or to protect the various colored finishes.

Baked Finishes—The excellent adhesion and imperviousness possessed by the "baking type" materials make them well suited for use on magnesium. Schedules requiring baking temperatures up to 400°F. can be used on as-cast, aged, or wrought parts, while a maximum temperature of approximately 225°F. should be used on solution heat treated castings in order to avoid aging or precipitation heat treatment. Baked finishes are recommended for die castings, small sand castings, and other parts of convenient size, since the adhesion thus obtained is better than with air dried materials. Improved service performance can likewise be obtained by forced drying or baking of most air drying primers and finish coats based on synthetic resins.

Assembly Protection

Inclosed Type Structures—Protection should likewise be given prior to assembly, to all castings, parts, and surfaces that are concealed or inaccessible in the completed structure. This applies to the interior of castings such as aircraft wheels, which are not tightly sealed from external atmospheric conditions; also to castings which may be completely inside more or less inclosed locations, for example, aircraft control brackets mounted within wing structures.

Metal-to-Metal and Metal-to-Wood Contacts—Where magnesium is assembled in contact with magnesium, a different metal, or wood, there is a possibility of corrosion occurring from moisture condensation, galvanic action, or attack by acids or salts which may be leached from the wood. Iron and wood are particularly bad; the former on account of the galvanic action between it and magnesium, and the latter on account of its porous nature and tendency to retain moisture. Such trouble may be avoided by the use of asphalt paint or similar sealing materials. Rivets, bolts, screws, or washers should be coated with asphalt type paint just prior to use. Special conditions requiring a solid insulating material may employ Bakelite, sheet rubber, or cork gasket material.

Cleaning Assembled Structures—Excess asphaltic and bituminous sealing compounds that have been squeezed out between joined surfaces and around rivet or

Paint Schedule for Magnesium Alloys¹

Service Condition	Surface Preparation	Primer ²	Finish ³
Interior	Remove dirt and grease. Chrome pickle, Navy Spec. PT-3	One coat of zinc chromate primer meeting Navy Spec. P-27, or one coat of a metal primer possessing max. adhesion as shown by test.	One or more coats of good quality oil paint or enamel. Lacquers must be used judiciously because of their low expansion and brittleness.
Exterior	Remove dirt and grease. Chrome pickle, Navy Spec. PT-3	One coat of zinc chromate primer meeting Navy Spec. P-27, or one coat of a metal primer possessing max. adhesion as shown by test.	Two or more coats of enamel characterized by high durability such as the synthetic resin enamels of the phenolic or glycerol phthalate type meeting Navy Spec. M-67 and E-5 respectively, or two or more coats of the same type varnish meeting Navy Spec. V-10 and V-11 pigmented with 1½-2 lb. of aluminum paste per gal.
Seaboard	Remove dirt and grease. Chrome pickle, Navy Spec. PT-3	One or two coats of zinc chromate primer meeting Navy Spec. P-23 or, preferably, Navy Spec. P-27.	Three or more coats of synthetic resin enamel of phenolic type meeting Navy Spec. M-67 or three coats of synthetic resin varnish of phenolic type meeting Navy Spec. V-10 pigmented with 1½-2 lb. of aluminum paste per gal.

¹Baked finishes are recommended where adaptable (see text).²Synthetic resin primers and finishes are generally improved by a forced drying of each coat for 1 hr. at 225-250°F. A surfacer or filler coat may be used over the primer coat when smoothness and appearance are of importance.³A surfacer or filler coat may be used over the primer coat when smoothness and appearance are of importance.

bolt heads, must be removed prior to painting, since they are likely to bleed through subsequent paint coatings. This is readily accomplished through the use of a commercial retarder thinner or with similar and less expensive materials, such as butyl alcohol, butyl acetate, or naphtha. A final naphtha or similar solvent wipe should be given the completed assembly immediately prior to painting.

The basic principle in the protection of magnesium alloy parts is to keep the metal as dry as possible through proper design which eliminates moisture-retaining pockets and joints, through the use of sealing paints or compounds, and through the use of impervious paints applied over corrosion inhibitive chemical coatings. When this has been done, no trouble should be experienced in securing adequate protection of the metal.

The Nickel Industry

By A. J. Wadhams*

Nickel was used by ancient man in swords and implements fashioned from nickel-bearing meteorites and in coins made from paktong, a nickel-copper alloy derived from China. It was extracted as an element in 1751 by Axel F. Cronstedt and named nickel from the ore "kupfer-nickel," so-called by superstitious miners who believed the ore bedeviled. The modern nickel industry dates from the opening of the New Caledonia mines in 1875 and those of Sudbury, Ontario, in 1886.

Occurrence—Commercial nickel ores fall into three major classes: (1) Sulphide ores, represented chiefly by the pyrrhotite-pentlandite-chalcocopyrite ores of Canada and Norway. Pentlandite, a complex nickel-iron sulphide, is the nickel carrier. Small quantities of ores of this type have been mined in Connecticut, Pennsylvania, California, Missouri, and in Sweden, Finland, Italy, China, Tasmania, South Africa, and Great Britain. (2) Oxidized ores of the garnierite (silicate) type, occurring in New Caledonia, and in small quantities on the border of North Carolina and Tennessee. Similar ores occur in Borneo, Madagascar, Brazil, Spain, Greece, Russia, the West Indies, and Oregon. (3) Arsenical ores, found in Ontario, Colorado, New Mexico, Saxony, Bohemia, France, and eastern India. Small percentages of nickel are also present in many of the copper ores, in manganese ores of the early class known as wad, and in nickeliferous ores such as those of Cuba.

Smelting and Refining—In the Orford process, the ore is ground fine, classified, roasted in Nichols-Herreschoff roasters, and smelted in reverberatory furnaces to remove a large part of the sulphur. The molten matte is charged into converters with silicious flux to produce a fluid slag which carries off the iron. The resultant nickel-copper Bessemer matte is smelted in a blast furnace with an alkaline sulphide flux and subsequently cast into large pots. The product solidifies in two layers. The top layer contains copper sulphide; the bottom layer contains nickel sulphide. Re-smelting with nitre cake and excess coke progressively purifies the product. The copper is blown to blister in basic lined converters and refined electrolytically. The nickel sulphide bottoms are crushed, leached and sintered, melted in reverberatory furnaces and cast into anodes. By electrolytic refining in a continuously purified nickel sulphate electrolyte, cathode nickel having a purity of 99.95% (plus cobalt) is obtained. The cobalt content range is 0.30-0.50%. Impurities may be copper, iron, carbon, sulphur, and silicon.

In the Mond process, crushed nickel sulphide bottoms are calcined to drive off sulphur, reduced to metal, and then treated with carbon monoxide gas, which forms a volatile nickel compound (nickel carbonyl) at 60°C. The nickel-laden gas is passed over pure nickel pellets at a higher temperature (about 180°C.). Metallic nickel is deposited on the pellets and the regenerated carbon monoxide is returned for use again as a nickel carrier.

The New Caledonian silicate ore is smelted to matte. Sulphur is supplied by adding gypsum or any alkaline sulphide to the furnace. The matte is blown to a high grade in Bessemer converters and the iron eliminated in the slag. After roasting to drive off the sulphur, the oxide is made into a plastic with reducing materials and produced in the shape of cubes or rondelles.

Products—Nickel is marketed in various forms as follows: (1) Nickel pellets produced by decomposition of nickel carbonyl gas without fusion; (2) electrolytic cathode sheets cut into various sizes; (3) blocks or shot obtained by remelting electrolytic nickel cast into pig molds or poured into water without deoxidation; (4) malleable nickel produced by pouring into ingot molds after deoxidation; (5) nickel cubes or rondelles reduced from the oxide without fusion; (6) nickel salts; (7) nickel oxide; (8) nickel powder.

Uses—Nickel is used in the food processing, radio, and chemical industries, in coinage, in the Edison storage battery, and as a catalyst in the hydrogenation of unsaturated organic compounds. Nickel plating is extensively employed and regularly forms a base layer for chromium plating. Heavy nickel plating has been developed for building up the worn parts of machinery, and a hard plate (up to 400 Brinell) is utilized for applications requiring unusual resistance to abrasive wear. Nickel clad steel has been developed for the construction of heavy tanks and kettles.

* Vice president, The International Nickel Co., Inc., New York.

Nickel finds its most extensive application as an alloying element in ferrous and nonferrous alloys. Table I serves to indicate the percentage distribution of nickel in the various metal markets and Fig. 1 shows the world production.

Fig. 1—World nickel production, 1870-1936.

60% nickel and 15% chromium is used in electrical resistance heating elements. An 80% nickel, 14% chromium, 6% iron alloy has good strength, toughness, and corrosion and oxidation resistance. It finds application in chemical and food processing equipment.

Table I
Approximate World Nickel Consumption

Construction steels, stainless steels and other corrosion and heat resisting steels, and steel castings	80%
Nickel cast iron	3%
Nickel-iron alloys	1%
Nickel-copper alloys and nickel silvers	14%
Nickel brass, bronze, and aluminum alloy castings	2%
Heat resistant and electrical resistance alloys	3%
Malleable nickel, nickel clad	9%
Electrodeposition	6%
Nickel salts, ceramic materials, storage battery materials and catalysts	1%
Miscellaneous and unclassified	1%

A variety of nickel-iron alloys have special thermal, magnetic, electrical, and elastic properties. Invar, containing 36% nickel and possessing a coefficient of thermal expansion of approximately zero, is one of this series. A 20% nickel alloy containing aluminum and cobalt has been developed for permanent magnets.

Monel is a copper-nickel alloy containing 67% nickel, 30% copper, the balance mostly iron and manganese. It is obtained by roasting copper-nickel converter matte and reducing the resulting oxide to metal with charcoal. This alloy is primarily a corrosion resistant alloy for handling acids, alkalies, brines, waters, and food products, and is resistant to exposure in dry and moist atmospheres.

Nickel is one of the chief alloying elements of the alloy steel industry. Its most outstanding characteristic is its ability to impart to steel increased hardness, strength, and toughness without sacrifice of ductility. Nickel steels find extensive application in the transportation field, in the oil and power industries, and in machine tool, agricultural and general machinery construction. In cast iron, nickel possesses the added advantage of refining the grain, promoting homogeneity and density, and reducing the tendency to chill. Special nickel cast irons have been developed for abrasion resistance and for heat and corrosion resistant applications.

Nickel-chromium steels carrying high percentages of the alloying elements form a series of corrosion and heat resistant alloys. The most popular of these, 18-8, contains 18% chromium and 8-10% nickel. A ferrous alloy containing

Nickel-copper alloys containing 20-30% nickel are used for condenser tubes handling sea water. A 25% nickel alloy is used for the United States' five cent coin. An alloy containing 45-55% nickel is marketed under a variety of trade names for pyrometer and electrical resistance wire.

The effect of nickel as a decolorizer is utilized in the nickel silvers, widely employed for architectural trim and plumbing fixtures, and finds application in the production of white gold. Nickel up to 2% is also used in several of the aluminum alloys including sand cast, permanent mold, die cast, and wrought products.

The approximate compositions and melting points of the nickel alloys used for melting in the nonferrous industry are as follows:

	Electrolytic nickel cathode	Shot and ingot from electrolytic nickel	Nickel- copper shot	Copper- nickel shot	High nickel- copper shot and blocks
Nickel (Plus Cobalt)	99.95%	99.60%	66.65%	50.07%	67.00%
Iron	0.01-0.04%	0.07%	0.66%	0.10%	1.75%
Copper	0.01-0.03%	0.026%	32.29%	49.57%	29.00%
Carbon	trace	0.11%	0.19%	0.06%	0.20%
Silicon	trace	0.11%	0.055%	0.04%	1.25%
Sulphur	trace	0.01%	0.017%	0.02%	0.01%
Manganese	0.13%	0.06%	0.75%
Melt Point, °F.	2650	2600	2400	2250	2460

Constitution of Nickel-Aluminum Alloys

By R. H. Schaefer*

For many years the only published diagram of this system was that of Gwyer¹ who was mainly interested in aluminum-rich alloys. In 1934 Fink and Willey² examined alloys containing up to 18% nickel and made a careful determination of

Fig. 1—Nickel-aluminum constitution diagram.

Fig. 2—Nickel end of the nickel-aluminum constitution diagram.

the eutectic temperature and composition, and the solid solubility of nickel in aluminum at various temperatures. These data are reported on p. 1230 of this Handbook. However, except for Bradley and Taylor's X-ray data which relates mainly to the phase limits at room temperature and to the atomic structure of the

*Metallurgist, The International Nickel Co., Research Laboratory, Bayonne, N. J.

various phases, it was not until 1937 that the whole system was re-investigated by Alexander and Vaughan,⁴ whose careful work included thermal analysis, microscopical examination and hardness measurements. Their diagram, with the exception of a slight modification of the NiAl boundary on the nickel side is shown in Fig. 1 and 2.

Both Bradley and Taylor, and Alexander and Vaughan agree that below 700°C. nickel forms a face-centered cubic terminal solid solution up to about 5% aluminum, that a two phase region exists between 5-13.3% aluminum, and that a face-centered cubic intermediate phase or Ni₃Al forms between 13.3-15.5% aluminum. However, the former authors, on the basis of X-ray data secured on quenched powder samples, concluded that the two face-centered phases showed increased mutual solubility at higher temperatures so that at 1100°C. the duplex field between 5-13.3% aluminum disappeared as opposed to the interpretation given in Fig. 1 and 2. Because of the possibility of losing aluminum through oxidation of the heated powder samples which would move the composition of the alloys towards the alpha field, and what appears to the author to be inconsistencies in the data of Bradley and Taylor when evaluated on the basis of their proposed equilibria, the interpretation of Alexander and Vaughan has been used. The Ni₃Al phase is reported to have a superlattice with aluminum atoms occupying the cube corners and nickel atoms the centers of the cube faces.

Fig. 3—Effect of aluminum on the Curie temperature of nickel.

contains 31.5% aluminum. The nickel-rich limit of this phase from about 1100°C. down is based upon the room temperature value of 23.5% aluminum reported by Bradley and Taylor since the alloys prepared by Alexander and Vaughan were quite widely spaced in this region.

At a somewhat higher aluminum content the intermediate Ni₃Al, which was originally thought by Gwyer to be NiAl, is formed by a peritectic reaction between NiAl and the liquid at 1133°C. This phase has a pseudo cubic structure with aluminum atoms lying very near to the cube corners and nickel atoms at the centers of two-thirds of the cubes. At 854°C. and 58% aluminum the intermediate phase NiAl, is formed by a peritectic reaction between Ni₃Al and the liquid. The intermediate phase NiAl, is the only one in the system which does not tolerate either excess aluminum or nickel. The structure of this phase appears to be orthorhombic with a unit cell consisting of four nickel atoms and twelve aluminum atoms.

The effect of aluminum on the Curie temperature of nickel is shown in Fig. 3 which is reproduced from the work of Marian.⁵ The abrupt knee in the curve at about 6% aluminum results when the limit of the alpha solution field is reached and may occur at a slightly lower aluminum content than indicated.

Constitution of Nickel-Beryllium Alloys

By D. E. Ackerman*

Although the age hardening properties of the nickel-beryllium alloys have been studied by a number of investigators, our knowledge of the theoretical aspects of the system is based, for the most part, upon the work of Masing and Dahl¹ who confined their attention to the nickel-rich end of the system. More recently Gerlach² has checked the lower temperature course of Masing and Dahl's alpha field boundary and has extended the boundary to lower temperatures. The two sets of data are in excellent agreement in the ranges in which they overlap.

The present constitution diagram is reproduced in Fig. 1. Small beryllium additions rapidly depress the liquidus temperature from 1455°C. for pure nickel to 1157°C. at 5.1% beryllium; at the latter point an eutectic of the saturated solid solution,

Fig. 1—Nickel-beryllium constitution diagram.

containing 2.8% beryllium, and the compound NiBe is formed. The liquidus temperature again rises as the beryllium content is increased above 5.1%; presumably, this increase continues until the melting point or decomposition temperature of the compound NiBe is reached.

The solubility of beryllium in nickel decreases markedly with decrease in temperature, ranging from 2.8% beryllium at the eutectic temperature (1157°C.) to 0.3% beryllium at 450°C.

Constitution of Nickel-Carbon Alloys

By R. H. Schaefer* and T. E. Kihlgren*

Our knowledge of this system arises principally from the work of O. Ruff in collaboration with various other investigators^{1, 2, 3, 4} and the later studies of T. Kasé.⁵ In Fig. 1, the liquidus curves and the eutectic horizontal are based on the combined data of Kasé and those of Ruff and his collaborators. The alpha solid solubility curve between 1250 and 995°C. was obtained from data secured at the International Nickel Co. Research Laboratory. The magnetic transformation curve is based on Kasé's data.

Fig. 1—Nickel-carbon constitution diagram.

graphitic and total carbon. The carbon in solid solution was obtained by difference. The alpha phase boundary of Fig. 1 is based on these data which are shown below, the deviation between the two sets of determinations varying from 0 to 0.03% C.:

Determination of Carbon Solid Solubility

Temperature, °C.	% Carbon in Solution	
	Sample No. 1*	Sample No. 2†
993	26	23
1135	35	35
1256	47	
1264		.47
1307	.58	...

*Contains 0.076% Si, about 0.65% total carbon (after homogenization)

†Contains 0.10% Si, about 1.30% total carbon (after homogenization)

The solid solubility at the eutectic temperature is apparently of the order of 0.65% carbon. The curve has been extrapolated from 995°C. to room temperatures, to agree with the data reported by the Bureau of Standards.

The liquidus temperature reaches a minimum at the eutectic temperature 1318°C. at 2.22% carbon and as the eutectic concentration is exceeded, the liquidus temperature is raised. Ruff and Kasé are in good agreement on the liquidus of alloys containing up to about 2.9% carbon, beyond which Kasé presents no data. The studies of Ruff and Martin⁶ extended to higher carbon contents and indicated that the liquidus increases with the carbon content to about 6.42% carbon at which there is a sharp break in the curve. This carbon content corresponds to the compound Ni_3C which Ruff and Martin⁶ consider to exist between 1500 and 2500°C., but which is readily decomposed. Their data are indicated in the tabulation:

*Metallurgists, The International Nickel Co., Research Lab., Bayonne, N. J.

Temperature, °C.	Total carbon dissolved, %
1560	2.50
1640	2.69
1640	2.73
1744	2.98
1842	3.38
1950	4.04
1956	3.97
2050	5.30
2100	6.42
2200	6.38
2200	6.30
2300	6.32
2400	6.31
2500	6.30

Ruff and Gersten⁵ determined the heat of formation of Ni_3C to be -394 ± 10 calories and concluded that this compound, being highly endothermic, is extremely unstable. Nickel carbide has not been observed as a constituent in commercial grades of nickel, confirming the view that if a carbide of nickel does exist, it is indeed unstable.

The data on the magnetic transformation of nickel-carbon alloys are not very satisfactory, Kasé's magnetic analysis having been made on chill cast unhomogenized specimens. Repeat runs were made on two alloys and these showed a gradual increase in the Curie temperature due presumably to a closer approach to equilibrium. The data indicate that the magnetic transformation of nickel is depressed by carbon to about 350°C ., at the limit of solid solubility of carbon in nickel, and is apparently unaffected by further increases in carbon content.

Constitution of Nickel-Chromium Alloys

By E. M. Wise* and R. H. Schaefer**

The first attempt to establish the constitution of this alloy system was made by Voss¹ in 1908 who found a minimum in the melting curve at 42% nickel and at this composition found an eutectic-like structure which he ignored in his published diagram. The system was generally considered to be of the solid solution type, but with present knowledge that the structure of nickel is face-centered cubic and chromium body-centered, a continuous series of solid solutions would not be expected and microscopic^{2, 3} and X-ray^{4, 5} examination indeed showed evidence of limited mutual solubility. Despite the great industrial importance of the nickel-rich alloys, only in the past ten years has the system been thoroughly investigated.

There is now general agreement that the system comprises a nickel-rich and a chromium-rich solid solution and that the mutual solubility decreases with the temperature although some divergence exists regarding the low temperature domain of the two solid solutions, particularly that rich in nickel.^{6, 7, 8} This is to be expected in view of the difficulty of attaining equilibrium at low temperatures and due to the effect of impurities; and some slight revision in this region is to be expected in the course of time.

The recent investigation of Jenkins and associates⁹ was conducted with great care and precautions were taken to exclude impurities; for this reason their data are accepted and shown in Fig. 1. The melting point of chromium indicated (1830°C.) is based on Adcock's¹⁰ determination and is higher than that observed by others^{4, 10} but ties in well with the melting temperatures of the alloys studied by Jenkins. The melting temperature of the eutectic is 1343°C. and at this temperature about 47% of chromium is soluble in nickel. At lower temperatures a small decrease in solubility occurs, slightly in excess of 40% chromium being soluble at 900°C. Thirty-five per cent nickel is soluble in chromium at the eutectic temperature, but a marked reduction in solubility occurs at lower temperatures—perhaps 9% being soluble at 900°C.

Fig. 1—Nickel-chromium constitution diagram.

Fig. 2—Curie temperature of nickel-chromium alloys.

Due to the lack of determinations in a portion of the high temperature high chromium region plus the difficulties in high temperature thermometry, a portion of the liquidus and solidus has been dotted. Because of the difficulty in attaining

*Assistant Manager, and **Metallurgist, The International Nickel Co., Inc., Research Laboratory, Bayonne, N. J.

equilibrium at low temperatures and the possible effect of nitrogen and other contamination, the solid solubility line is dotted.

The magnetic change point (Curie temperature) is rapidly lowered by the addition of chromium to nickel, but some disagreement exists in the precise relationship.^{4, 7, 12} The recent investigation of Marian¹³ yields the results shown in Fig. 2 which are tentatively accepted.

Constitution of Nickel-Cobalt Alloys

By D. E. Ackerman*

The nickel-cobalt system was first studied by Guertler and Tammann¹ who found a continuous system of solid solutions, the solid alloys becoming nonmagnetic when heated above a critical temperature which increased with the cobalt content. The general features of the first investigation were confirmed by Ruer and Kaneko,² whose data on the temperatures of the magnetic transformation, liquidus and solidus are the most accurate. After correcting for the currently accepted values of the melting point and Curie temperatures of the pure metals these data have been plotted in Fig. 1. The liquidus rises slowly from 1455°C. at pure nickel to 1480°C. at pure cobalt; there is unanimous agreement that the liquidus and solidus nearly coincide and the single line (liquidus) shown on the diagram is to be considered as two lines having a maximum separation of possibly 2-3°C. at about 50% cobalt.

The Curie temperature rises continuously from 362°C. at pure nickel to 1125°C. at pure cobalt. Some doubt exists as to the exact Curie temperature of cobalt, various investigators^{3, 4, 5, 14, 17, 18, 19} reporting values varying from 1100°C.-1130°C. Strictly speaking, the Curie temperature curve in the figure marks the end of the magnetic transformation, alloys held at higher temperatures being nonmagnetic. The beginning of this transformation, which Ruer and Kaneko (as well as later experimenters) considered to involve no crystallographic change, is ill defined and rather dependent upon the details of the experimental technique and is therefore not indicated on the diagram. Steinwehr and Schulze¹¹ find the heat of the magnetic transformation to be 1.2 cal. per g.

In 1926 Masumoto⁷ announced the discovery of a new transformation in pure cobalt, the metal having a close packed hexagonal lattice at temperatures below about 400-440°C. and a face-centered cubic lattice at higher temperatures. Masumoto's four samples contained various amounts of impurities up to a maximum of 0.45%, chiefly nickel, iron, and carbon, the transformation temperature increasing somewhat with the purity of the specimen. The transformation was studied by means of thermal analysis, electrical conductivity, thermal expansion, magnetic tests, dilatometer tests and X-ray analysis. This transformation in pure cobalt has been observed by others (references 4-12, 17-21) and appears to occur at 440°C., although temperatures ranging from 399-475°C. have been given. Several investigators^{10, 14, 17} have commented upon the extreme sluggishness of the transformation from the hexagonal to cubic cobalt. This sluggishness is apparently related to the small heat of transformation (0.1 cal. per g.) found by Steinwehr and Schulze.¹¹

Masumoto's much less complete study of cast nickel-cobalt alloys annealed three hours at 1100°C. before testing, showed the temperature of this transformation to be depressed by nickel additions as shown by the boundary between the alpha and alpha + beta fields; the location of the alpha + beta, beta field boundary rests upon almost no experimental evidence; the boundaries between the alpha and the beta fields have not been checked to date and in view of the scanty and somewhat unreliable data upon which they are based their locations must be considered as tentative only.

The data of many investigators^{5, 7, 9, 10, 13, 14} suggest the existence of a structural transformation at some higher temperature, in the range of 800-1100°C., at which the face-centered cubic lattice formed at 440°C. again transforms to a hexagonal close packed lattice. These data are not concordant and their interpretation is complicated by the fact that structural transformations in cobalt are very sluggish and

Fig. 1—Nickel-cobalt constitution diagram.

*Associate Professor of Metallurgy, Purdue University, Lafayette, Ind.

are markedly influenced by mechanical work. The careful work of Seybolt and Mathewson¹⁴ seems to support Cardwell's¹³ conclusion (from room-temperature X-ray data on quenched cobalt) that a transformation exists at 850°C. Marick,¹⁵ on the other hand, recently studied Cardwell's cobalt and concluded, on the basis of X-ray examination at high temperature, that the 850°C. transformation is nonexistent. Again, Sykes,¹⁶ using the technique of Hendricks, Jefferson and Schultz⁷ was able to check the observation of the latter investigators that a transformation occurred at 1020°C. but could detect no transformation in the 800-1100°C. range in cobalt by thermal means. In general, different investigators have used both different methods of study and cobalt prepared in widely different ways and of widely different purities, and a critical study of these various possible sources of disagreement would be highly desirable, for even among those adhering to a belief in a high temperature transformation there is considerable divergence of opinion as to the actual temperature. At present the weight of opinion seems to favor one structural transformation point, that at 440°C.

The lattice constants of the nickel-cobalt alloys have been measured by Osawa,¹⁷ those of metallic cobalt have also been determined by Van Horn. Osawa's value of "a" for nickel is in excellent agreement with that of McKeehan;¹⁸ the divergence in the constants for pure cobalt may be related to the different methods used in preparing the specimens.

Lattice Constants of Nickel-Cobalt Alloys and of Cobalt

% Ni	Lattice	a	c	c/a	Investigator
100	Face-centered cubic	3.508	Osawa

Constitution of Nickel-Manganese Alloys

By N. B. Pilling*

The nickel-manganese series has received attention from but few investigators even though the lower manganese content alloys are of some technological importance. The early (1908) diagram of Zemczuzny, Urasow and Rykowski¹ represented a continuous series of solid solutions with a minimum in the liquidus. Dourdine,² confirming the general aspects of the liquidus curve with a purer set of alloys, found (1915) microscopic evidence of heterogeneity in the range from 38-71% manganese and detected a complicated series of solid transformations within this same range. In this fragmentary state the diagram rested until quite recently.

Dourdine² resumed his study of this series and in 1932 published a revision of his earlier diagram. This is represented in Fig. 1. In many respects it must be regarded as tentative, yet it suggests the following relations. Mn dissolves in Ni, at temperatures exceeding about 760°C., up to 43%; at temperatures below this the solid solutions containing more than 36% Mn undergo a transformation which appears to produce the compound Mn_3Ni_4 or epsilon phase. At about 48% Mn the delta phase occurs, which at temperatures approaching the solidus, corresponds to the compound $MnNi$; the solubility of this phase for Ni changes but slightly with temperature down to 600°C., while its solubility for Mn increases greatly as the temperature decreases. It is subject to a transformation at about 600°C., the significance of which has not yet become clear. The solubility of Mn for Ni, at temperatures approaching 1000°C., extends down to about 58% Mn, the limiting concentration being that of the compound Mn_3Ni_4 . This gamma phase, at concentrations lower in Mn than about 68%, transforms into the delta phase. The compound Mn_3Ni_4 , therefore, exists only within the limited temperature range of approximately 950-1000°C. Two fields of duplex alloys occur (beta + delta) and (delta + gamma). The former is complicated by solid transformations affecting both phases; the limiting concentrations of the latter change considerably with temperature and have not as yet been traced out fully.

Fig. 1—Nickel-Manganese Constitution Diagram.

The constitution of the alloys quite rich in Mn has evidently not been studied. Manganese undergoes a number of transformations in the solid state, recent work³ indicating three modifications:

Alpha Mn	cubic	under 742°C.	8.894A
Beta Mn	cubic	742°-1191°C.	6.300A
Gamma Mn	tetragonal	above 1191°C.	{3.774A 3.526

Dourdine reports⁴ that under ordinary rates of cooling from solidification an unstable state persists, resulting in a fictitious appearance, of complete miscibility between Ni and Mn, the delta phase and related heterogeneous fields being suppressed. A more or less prolonged heating at temperatures in the vicinity of the solidus is required for the development of that state which permits the formation of the stable phases represented on the diagram.

Manganese depresses the magnetic transformation temperature of Ni,⁴ 17% Mn sufficing to lower it to room temperature. The alloys containing 12-40% Mn can

*International Nickel Co., Inc., Bayonne, N. J.

be transformed⁷ by long heat treatment below 450°C. to a strongly ferromagnetic state, the change occurring without structural alteration.

The Constitution of the Nickel-Molybdenum Alloys

R. H. Schaefer*

This system was first investigated by Baar¹ by thermal analysis and microscopical methods. He reported a nickel-rich solution of molybdenum, an eutectic at 1305°C. and 49% molybdenum, and the peritectic formation of the compound NiMo at 1345°C. and 62% molybdenum. Dreiholz² later confirmed the peritectic formation of the compound, but found the eutectic temperature to be 1315°C. He also determined the effect of molybdenum on the Curie temperature of nickel which was lowered to room temperature by the addition of 18% molybdenum.

At 1305°C. the solubility of molybdenum in nickel was placed at about 32% by Baar, based upon the appearance of a cooling curve arrest in a 35% molybdenum alloy which was not found in an alloy containing only 30% molybdenum. The limit of this alpha solid solution field was shown to decrease at lower temperatures by Koster and Schmidt,³ who reported a solubility limit of 18% molybdenum at 800°C.

Recently the first really comprehensive study of this system was published in two parts by Grube and Schlecht⁴ and Grube and Winkler,⁵ who discovered several

Fig. 1—Nickel-molybdenum constitution diagram.

Fig. 2—Effect of molybdenum on the Curie temperature of nickel.

new fields. The alloys were prepared from quite pure nickel and molybdenum powders,[†] and carefully pressed and sintered.⁶ Depending upon the molybdenum content of the alloys, they were then cold rolled, hot rolled or heated to incipient fusion to seal any fissures, homogenized for 48 hr. at 1280°C., and furnace cooled to room temperature in from 10-14 days. As a result of hardness, electrical resistance, magnetic susceptibility, corrosion resistance measurements, X-ray and microscopical examination, they reported the constitution diagram which is reproduced in Fig. 1.

In general the above work agrees quite well with Baar's data at temperatures above 925°C., but below this temperature two new phases are reported. The face-centered cubic alpha solid solution starts to transform at 875°C. to an ordered face-centered tetragonal β phase which possesses a superlattice. A very small

*Metallurgist, The International Nickel Co., Inc., Research Laboratory, Bayonne, N. J.

[†]The nickel contained 0.04% C., 0.12% Fe, 0.08% O₂, and was sulphur free. The molybdenum was 99.9% pure.

heterogeneous region $\alpha + \beta$ exists between the two fields. At room temperature the β field is shown to extend from approximately 18-29% molybdenum. The latter concentration happens to be approximately that of Ni_3Mo , so that the β phase might be considered to be a solution of nickel in Ni_3Mo . The dimensions of the unit cell of the 29% molybdenum alloy are reported to be $a = 3.61 \text{ \AA}$ and $\frac{c}{a} = 0.98$.

At 35.3% molybdenum and 925°C . a peritectoid reaction occurs between the alpha solid solution and the compound NiMo yielding the compound Ni_3Mo . The latter has a close packed hexagonal lattice with $a = 2.54 \text{ \AA}$ and $\frac{c}{a} = 1.65$. The compound NiMo which occurs at 62% molybdenum is said to have a very complicated structure which has not as yet been determined.

Grube and his co-workers attempted to determine by X-ray methods whether any solid solution occurred on the molybdenum end of the diagram. They found no increase in the lattice constant of pure molybdenum ($a = 3.1374 \text{ \AA}$) in alloys containing 1-20% nickel and therefore concluded that no appreciable solubility exists. However, the unpublished work of W. P. Sykes¹ and C. A. Brashares indicates that at 1400°C . approximately 0.5% nickel is soluble in molybdenum. The latter investigators also reported the eutectic and peritectic temperatures to be $1345 \pm 10^\circ\text{C}$. and $1400 \pm 10^\circ\text{C}$., respectively, which are somewhat higher than those found by Baar and Grube.

The effect of molybdenum on the Curie temperature of pure nickel is shown in Fig. 2. This is based upon the work of Marian² and Grube³, who agree that 10-11% molybdenum is necessary to lower the magnetic transformation to 0°C .

Constitution of Nickel-Silicon Alloys

By D. E. Ackerman*

Only two investigations of the complete nickel-silicon system have been made; the first by Guertler and Tammann,¹ the second by Iwase and Okamoto.² The first study was based chiefly upon thermal and microscopical methods while the second utilized thermal analysis, microscopy, X-rays and magnetic analysis. Unfortunately, the published accounts of both researches fail to make clear what precautions, if any, were taken to insure that the specimens tested were in complete equilibrium. Comparison of data from several available studies of restricted portions of the diagram with those cited above give rise to some doubts as to the accuracy of the latter. While there is thus little specific grounds for choice, even between the

two available comprehensive studies, the data of Iwase and Okamoto have been chosen as the basis for the present diagram, chiefly because they are the more recent, the more numerous and were obtained by more different types of experimentation. Several features of the diagram (the course of the alpha field boundary and the existence of Ni_3Si and NiSi) are rather well established. Guertler, Iwase and Okamoto also postulate the existence, at some temperature, of Ni_2Si and Ni_5Si_3 , but the remainder of the diagram must be considered tentative only. The uncertainties are both qualitative and quantitative in nature. The data available up to 1936 have been critically reviewed elsewhere.³

The location of the high-temperature (800-1100°C.) portion of the α field boundary is based upon the careful X-ray work of Blumenthal and Hansen⁴ while the remainder of the boundary utilizes the data resulting from the painstaking hardness, electrical resistance and microscopical data of Dahl and Schwartz.⁴ The alloys used by the latter contained 0.5% manganese and 0.05% magnesium as deoxidizers. At room temperature the maximum solid solubility of silicon in nickel appears to be about 6.0%.

The liquidus curve for the system exhibits four eutectics as follows:

$\alpha + \beta$	melting at 1151°C. and containing 11.5% Si
$\text{Ni}_3\text{Si}_2 + \text{Ni}_2\text{Si}$	" " 1242 " " 17.5
$\gamma + \text{NiSi}$	" " 964 " " 29.0
$\text{NiSi} + \text{NiSi}_2$	" " 986 " " 38.0

Three intermetallic compounds which melt without decomposition are also indicated

Ni_3Si_2	melting at 1256°C. and containing 16.0% silicon
Ni_2Si	" " 1284 " " 19.3
NiSi	" " 990 " " 32.4

Two intermetallic compounds formed by peritectic reactions are also postulated:

$\beta(\text{Ni}_3\text{Si} + \text{Ni})$	formed at 1163°C. by reaction between Ni_3Si_2 and 12% Si melt
NiSi_2	" " 993 " " δ " 41.5% Si melt

NiSi_2 undergoes a polymorphic change at 981°C.

The α solid solution has been discussed. The presence of a β solid solution, consisting of Ni_3Si which may dissolve excess nickel, appears to be consistent with Iwase and Okamoto's data on duration of the thermal arrest at 1151°C., but no microscopical or other data supporting such a field have been presented; it is

Fig. 1—Nickel-silicon constitution diagram.

*Associate Professor of Metallurgy, Purdue University, Lafayette, Ind.

retained simply because it represents the most general case possible with the data available. β is indicated as decomposing eutectoidally at 1120°C. The γ solid solution may be considered to consist of a solid solution of silicon in Ni_3Si (which undergoes a polymorphic change at 1214°C). γ undergoes an eutectoid transformation at 806°C., yielding Ni_3Si and Ni_2Si ; the latter may form at 845°C. by a peritectoid reaction between NiSi and γ . None of the investigators of this system except Guertler¹¹ suggest the possible solid solubility of nickel in silicon, but a limited solid solution of nickel in silicon, designated δ , has been included in the diagram.

Oelsen and Samson-Himmelstjerna⁸ have obtained the heat of formation-composition curve and the heat content-composition curve for the system and find only two breaks which would indicate compounds which melt without decomposition. The heats of formation of these are:

Ni_2Si	33.6 kg. cal./g. mol.
NiSi	20.6 " " "

The identification of these two, and only these two, stable compounds supports these features of Guertler and Tammann's work. Apparently they obtained no evidence of the existence of the Ni_3Si proposed by Iwase and Okamoto. Oelsen and Samson-Himmelstjerna confirmed the existence of Ni_3Si , whose heat of formation is the sum of those of Ni_2Si and NiSi and which they therefore regard as a double silicide. They also confirm the existence of Ni_3Si and Ni_2Si , the latter being indicated on Guertler and Tammann's diagram but not on that of Iwase and Okamoto.

Many of the basic facts regarding the system are thus in dispute and a carefully conducted, comprehensive study of the system is required. It may be pointed out that the only study of the lattice constants of the various phases is the work of Boren⁷ who found NiSi to be structurally similar to FeSi (tetrahedral cubic) and to have a lattice parameter of 4.437Å although this value may be in error because of the diffusedness of the line edges.

Several determinations of the effect of silicon upon the Curie point of nickel are available; aside from the data of Manders,⁸ which are rather irregular, the data are fairly consistent although those of Dahl and Schwartz⁹ show a less rapid drop in Curie temperature with silicon content than the data of Kusemann and Scharnow¹⁰ and of Marian,¹⁰ both of which agree well with each other and with the data of Iwase and Okamoto.³ A weighted mean of the better data follows:

% Silicon	Curie Temperature
0	362°C.
1	320
2	263
3	195
4	130
5	45
6	-45

The Constitution of Nickel-Sulphur Alloys

By D. E. Ackerman*

The first and only study of the constitution of the binary nickel-sulphur alloys is that of Bornemann,¹ who examined nickel alloys containing from 0-31% sulphur. The sulphur volatilizes from richer melts too fast to permit study. The diagram was based almost entirely upon thermal analysis, although a few confirmatory microscopical examinations in some of the larger fields were made. Sulphur was found by Bornemann to have a maximum solubility of 0.5% in solid nickel at 644°C., but to be insoluble below 532°C. A strongly marked eutectic of alpha (solid solution of sulphur in nickel) and beta (solid solution containing Ni_3S_2) was found at 21.5% sulphur and 644°C. Between 24 and 31% sulphur and 520 and 810°C., the beta solid solution containing Ni_3S_2 occurred. At lower temperatures but at the same sulphur contents a considerable number of phase fields of restricted area were indicated, but the existence of these may be questioned, since it is not clear that the pretreatment of the specimens was such as to insure freedom from segregation, which, at the sulphur contents involved, might be expected to be present in the original castings on a considerable scale. The reality of the thermal arrests upon which these small fields were based cannot be questioned, but it may be suggested that some of them originated in the successive transformation of variously segregated regions in each of the several specimens.

The eutectic at 21.5% sulphur and 644°C. has been directly observed by several investigators, among whom may be mentioned Hayward,² Vogel and Tonn,³ and Merica and Waltenberg,⁴ and has been inferred by others.^{4,5} As the result of a study of portions of the ternary iron-nickel-sulphur system Guertler and Savelsberg⁶ have, by extrapolation, suggested a binary nickel-sulphur constitution diagram which differs, particularly in the higher sulphur ranges, from that of Bornemann. Unfortunately, few experimental details are given.

The accompanying constitution diagram is based chiefly upon the work of Bornemann and of Guertler and Savelsberg, although the careful work of Merica and Waltenberg has been taken into consideration in provisionally locating the limits of the alpha field. The latter investigators, working with unhomogenized, cast nickel-sulphur alloys, found the eutectic arrest at 644°C. in alloys containing more than about 0.03% sulphur, but could detect heterogeneity by microscopic examination with as little as 0.005% sulphur. These data suggest, first, that at low sulphur contents the microscopical method may be more sensitive than the thermal method, relied upon by Bornemann for determining the range of the alpha field. Second, the true solid solubility of sulphur in nickel must be considerably lower than reported by Bornemann. The presence of microscopically visible sulphide in the 0.005% sulphur, as cast specimens of Merica and Waltenberg, may be ascribed to a local sulphur content, produced by segregation effects, in excess of the solid solubility limit. In view of the low nominal sulphur content and the small size of the melts it appears quite improbable that local sulphur contents resulting from segregation would be more than twice the average sulphur content. A value of 0.01% sulphur is thus suggested as the solid solubility of sulphur in nickel at 644°C. While this value has been used in the diagram it should probably be considered as the upper limit of the possible solid solubility, for the forging tests of Merica and Waltenberg and of others indicate that the value should be even lower. The insolubility of sulphur in nickel below about 532°C. is based almost entirely upon the general nature of the diagram and upon the fact that, according to Bornemann, the Curie point of nickel is not shifted by moderate sulphur contents.

Constitution of Nickel-Sulphur Alloys.

*Associate Professor of Metallurgy, Purdue University, Lafayette, Ind.

As mentioned above, the eutectic of alpha (whether nickel or a dilute solution of sulphur in nickel) and beta at 21.5% sulphur and 644°C. is well established. The beta phase is a solid solution containing the compound Ni_3S_2 , the latter solidifying at 787°C. Because of the lack of experimental data the exact nature of the solid alloys, containing higher sulphur contents than the beta phase, is not known, but a solid solution apparently exists which decomposes at 550°C. with the formation of a compound, possibly Ni_2S_3 , which has been designated gamma. The beta phase breaks down at 532°C. with the formation of nickel and gamma, the nickel undergoing a magnetic transformation at 362°C.

The liquidus is probably reasonably accurate from 0 to about 31% sulphur. The existence of the compound Ni_3S_2 is established. Alsen⁶ suggests it is cubic, with a value of $a = 4.08 \text{ \AA}$. The existence of the beta phase, but not, necessarily, its compositional range, may be accepted, and the same is true of the solid state transformations at 644°C. and at 532°C. The remainder of the diagram, including the nature and limits of the alpha phase, require further study. Indeed, a recheck of the entire system, using several modern methods for determining the extent of each of the several fields, would be most interesting, as the application of the now well developed theory of pressure-temperature-composition diagrams should permit extension of the binary diagram to considerably higher sulphur contents.

Constitution of Nickel-Tin Alloys

By J. T. Eash*

The nickel-tin system has been the subject of few investigations. Complete diagrams were reported by Gullet¹ in 1907 and by Voss² in 1908. Renewed interest has been shown in these alloys in recent years and in 1937, Mikulas, Thomassen and Upthegrove³ reported the results of their investigation of the complete system. While the interpretations given the diagrams of the three studies are quite different, the liquidus, the eutectic and peritectic temperatures agree fairly well. Jette and Fetz⁴ determined the limit of solubility of tin in nickel in 1935.

The constitution diagram shown in Fig. 1 is chiefly as given by Mikulas, Thomassen and Upthegrove.³ Thermal analyses, microscopic and X-ray examinations were used for the determinations. Hanson, Sandford and Stevens⁵ report the occurrence of a eutectic at 0.18% nickel at 232°C., the melting point of tin, between tin and a compound; however, Mikulas and associates found no evidence of a eutectic microstructure and conclude from analyses of quenched specimens the eutectic must contain less than 0.01% nickel.

The compound Ni_3Sn , containing 27.1% nickel is formed at 793°C. by the peritectic reaction with liquid and Ni_3Sn_2 . It has a density of 8.78. Mikulas reports it as having a complex lattice structure which was not determined. Fetz and Jette⁴ indicate that the phase probably exists over a narrow composition range.

By means of X-ray examinations, Fetz and Jette found a phase at 29.7% nickel which they called theta; however, they give no information regarding the mechanism of its formation.

Vigouroux⁶ was able to separate residues from two alloys by chemical methods and found them to contain 33.3% nickel which would correspond to the compound Ni_3Sn . From X-ray investigations, Oftedal⁷ and Fetz and Jette report the presence of phases corresponding to Ni_3Sn ; however, Mikulas found that an alloy of the Ni_3Sn composition which had been annealed 500 hr. at 500°C. contained two microscopic phases and concluded they were Ni_3Sn , and Ni_3Sn_2 .

At 43% nickel, Ni_3Sn_2 is formed. According to Mikulas it solidifies at 1253°C. Above 902°C. it has a body-centered tetragonal lattice structure with 10 molecules per cell where $a = 9.199$ Å, $c = 8.578$ Å and $c/a = 0.933$. Its density is 9.36. Below 902°C. it has a hexagonal modified nickel arsenide type of structure with 1 molecule per cell and $a = 4.092$ Å, $c = 5.186$ Å and $c/a = 1.267$ Å. Its density is 8.99.

The dotted line at 902°C. in the Ni_3Sn_2 + liquid field has been inserted by the writer to indicate the crystal change in the Ni_3Sn_2 phase which is inferred by the adjacent area of the diagram, but not shown in the literature.

The compound Ni_4Sn containing 60% nickel is formed at 1164°C. by the peritectic reaction between liquid and Ni_3Sn_2 .⁸ It has a density of 9.62. P. Rahlfs⁹ reports Ni_4Sn as having a hexagonal close packed lattice with a superstructure where $a = 2a = 5.275$ Å, $c = 4.234$ Å and $c/a = 1.606$. Fetz and Jette believe that both Ni_3Sn_2 and Ni_4Sn exist over very narrow composition ranges.

The peritectic reaction at 1143°C. between Ni_4Sn and liquid forms the compound Ni_5Sn containing 66.4% nickel. Ni_5Sn has a simple tetragonal lattice with 2 molecules per cell where $a = 5.111$ Å, $c = 4.881$ Å and $c/a = 0.955$. Its density is 9.15. Below 941°C. Ni_5Sn is unstable and forms Ni_3Sn and alpha solution.¹

The solubility of tin in nickel¹ decreases from about 18% at the eutectic temperature to 1.6% at 450°C. Jette and Fetz found that as a result of the change

Fig. 1—Nickel-tin constitution diagram.

*Research Metallurgist, Research Laboratory, The International Nickel Co., Inc., Bayonne, N. J.

in tin solubility with temperature, the alloys exceeding the alpha phase boundary could be age hardened. An alloy containing 20% tin had a hardness of 250 Brinell after quenching from 1050°C. and after aging 5 hr. at 600°C. a hardness of 490 Brinell.

The alpha solution has a face-centered cubic structure and its lattice parameter increases linearly from 3.515 Å to 3.602 Å between zero and 18.4% tin.^{3,4}

The magnetic transformation of nickel (358°C.) is lowered by the addition of tin as noted by Marian¹⁰ and others.^{1,2}

Constitution of Nickel-Zinc Alloys

By D. E. Ackerman*

The first attempt to determine the constitution of the nickel-zinc alloys appears to be that of Tafel,¹ who published a series of three papers on the subject, the first of which appeared in 1907. Binary alloys containing 50-100% zinc were studied, chiefly by thermal analysis, with some microscopical data. An eutectic was found at 418.5°C. (the melting point of zinc being taken as 419°C., that of copper as 1084°C.) and it was suggested that the eutectic point occurred at about 99.75% zinc; the liquidus then rose with decrease in zinc content to 873°C., where it became horizontal at about 77.5% zinc, rising again with further decrease in zinc content. The existence of the compounds NiZn and Ni₂Zn, was suggested and four horizontals below the liquidus were also located, as follows:

Temp., °C.	Range, % Zinc
418.5	100-88
640	70-54
780	53-50
870	72.5-61

As will be seen later, the designation of the higher zinc eutectic temperature as 418.5°C. is in close agreement with the best present day determinations. At higher temperatures and lower zinc contents Tafel's data become somewhat too low, the liquidus temperature at 60% zinc (1010°C.) being about 10° lower than, and the 780°C. horizontal about 25-30°C. below, the best recent data. These discrepancies appear to be due chiefly to insufficient precautions to insure complete equilibrium in the alloys before beginning the experimental work.

In his later papers Tafel attempted to predict the nature of the low zinc end of the binary diagram from data obtained in the study of the ternary copper-nickel-zinc alloys, and while this extrapolation provided, for many years, the only information available on this part of the diagram, it could not supply the need for direct experimental data. Nevertheless, Tafel's diagram foreshadowed the present diagram with considerable fidelity, and though far from complete is ample testimony to Tafel's experimental skill and theoretical intuition.

In 1908 Voss² examined the alloys containing 100-77% zinc; he confirmed the shape of Tafel's liquidus in this range except that he appears not to have found the eutectic at 99.75% zinc and thought the 418°C. horizontal to extend from 100-85.5% zinc.

Bornemann³ discussed some of the shortcomings of the work to date but supplied no constructive suggestions. Peirce⁴ found the high zinc eutectic at about 99.75% zinc and 419.4°C. and suggested a small (0.05%) solubility of nickel in zinc. Charrier⁵ reported a number of nickel-zinc compounds, not all of which are now thought to exist. Hafner⁶ suggested several changes in the diagram, but his data appeared not to warrant a modification of the latter. The constitution diagram which appeared in the International Critical Tables⁷ at about the same time was in close agreement with the diagram suggested somewhat later by Bauer and Hansen,⁸ who subjected the available information to an enlightening critical review which revealed the slender basis of experimental data upon which the accepted constitution diagram rested.

In 1932 Tamaru,⁹ and Heike, Schramm, and Vaupel,¹⁰ published their independent researches on the system; some of these data have been critically reviewed.¹¹ Tamaru

Fig. 1—The nickel-zinc constitution diagram.

*Associate Professor of Metallurgy, Purdue University, Lafayette, Ind.

and Osawa¹² re-examined the high zinc end of the diagram in more detail. Comparison of these reports reveal numerous discrepancies, some of major and others of minor importance; many of these appear to arise from the rather casual precautions taken in the Japanese work to avoid loss of zinc, to insure homogeneity and to minimize other similar sources of error. The rather satisfactory resolution and elimination of most of these discrepancies recently has been accomplished on theoretical and experimental grounds by Heike, Schramm and Vaupel¹³ and by Schramm¹⁴ and the diagram resulting from their careful work is the one offered here, although it is tentative in several respects.

The alpha solid solution extends from 0-28% zinc at room temperature and to 43.3% zinc at 1040°C. Heike, Schramm and Vaupel consider the β phase, which forms by a peritectic reaction at 1040°C. between saturated alpha solid solution and melt containing 55% zinc, to be a conventional solid solution. Below 810°C. to 675°C. (as the zinc content varies from 48-55%) there exists a β_1 phase the exact nature of which (whether a simple solid solution or, essentially, a compound NiZn) is not yet clear. The gamma phase consists of a solid solution based upon an intermetallic compound assumed, in this diagram, to be NiZn, though some investigators consider the basic compound to be $\text{Ni}_4\text{Zn}_{11}$ or $\text{Ni}_7\text{Zn}_{10}$. The gamma phase melts without decomposition at 881°C.; its compositional range shifts considerably with temperature. Below about 500°C. the gamma phase transforms into a Γ_1 phase if the zinc content is below 80%. This transformation was discovered by Schramm and requires some further work for its complete elucidation. The delta phase is an intermetallic compound $\text{Ni}_4\text{Zn}_{11}$, containing 10.4% nickel and forms as the result of a peritectic reaction at 490°C. between the saturated gamma solid solution (14.4% Ni) and the melt (ca. 2.0% Ni). This compound may hold a very small amount of excess nickel in solid solution. A nickel-rich solid solution containing up to 0.05% zinc comprises the eta phase; the solid solubility of zinc in the saturated solid solution is thought not to change with temperature. An eutectic between delta and eta occurs at 418.5°C. and 99.75% zinc.

The data of three groups of investigators^{9, 10, 11, 12, 14, 15} bear on the crystallographic nature of the various phases. The data of Caglioti and of the Japanese investigators are open to some question as it is not certain that proper precautions to insure constant composition and equilibrium conditions were taken in every case. The data of the German authors appear the most reliable though they are checked, in several instances, by data from the other sources.

The alpha phase is face-centered cubic, with a lattice parameter, for the saturated solid solution at room temperature, of 3.576 Å. The β phase cannot be retained at room temperature by quenching; high temperature X-ray analysis shows this phase to be body-centered cubic (CsCl type) with a lattice parameter of 2.908 Å. The β_1 phase is body-centered tetragonal, the lattice parameter-composition curves showing a maximum for "a" (2.7458 Å) and minima for "c" and "c"/"a" (3.1739 Å and 1.1559 respectively) at 52% zinc, the composition of the hypothetical compound NiZn. The lattice of the gamma phase is cubic, with 52 atoms in the unit cell; that of the Γ_1 phase is very similar and can be obtained by a very slight deformation of the gamma lattice. The lattice of the delta phase ($\text{Ni}_4\text{Zn}_{11}$) is hexagonal ($a = 8.855$ Å, $c = 14.603$ Å) and is likewise considered to be deformationally derivable from the gamma phase lattice.

The data on the effect of zinc upon the Curie temperature of nickel are taken from what appears to be the best⁹ of the several sets of data^{9, 10, 11} available on this point.

Physical Constants of Pure Nickel

By G. F. Geiger*

Introduction—The purity of electrolytically refined nickel is approximately 99.95% (includes cobalt). Electrolytically refined nickel of special purity, 99.99%, containing no cobalt, has been made in small quantities.¹⁴

The values assigned for the various physical constants or properties of metals are approximations only, based upon the best data available. Since the composition and structure of metals vary any single value assigned is estimated to be a typical or average value and should not be accepted as minimum, maximum, or specification values.

Fig. 1—Mean specific heat (0-20°C.) of Mond nickel (Umino).

Fig. 1A—True specific heat of pure nickel and Mond nickel (Umino).

Fig. 2—Thermal expansion of 99.94% nickel.¹⁴

Fig. 3—Effect of temperature on thermal conductivity (99.94% Ni).

Fig. 4—Electrical resistivity of 99.99% nickel.

Fig. 5—Thermoelectromotive force of nickel. Note Ni-Ag—on nickel wire no analysis given. Ni-Pt—calculated from results on the Ni-Ag and Ag-Pt. Ni-Cu on nickel wire of the composition: Cu 0.20, Co 0.15, Fe trace, C + Si none, impurities 0.35. Ni-Pb on Mond nickel.

Atomic Weight—The atomic number of nickel is 28. The atomic weight according to the American Chemical Society is 58.69. Two isotopes of nickel are known—58 and 60.

Atomic Radius—The atomic radius of pure nickel is 1.38×10^{-8} cm.²

Crystal Form—The crystal form of nickel is face-centered cubic at all temperatures. The edge of the cube³ is 3.51 Å (3.51×10^{-8} cm.).

*Development and Research Div., The International Nickel Co., Inc., New York.

(a) Single or limited number of determinations. (b) Average of many determinations.

¹⁴All references given at the end of the article on Properties of Commercially Pure Wrought "A" Nickel.

Density—The density (a) of pure nickel¹ (99.94%) is as follows:

Condition	Temperature, °C.	Density, g./c.c.
As cast	23	8.907
Cold swaged 23% reduction of area.....	25	8.901
Cold worked annealed at 950°C.....	25	8.902

Thermal Expansivity—The thermal expansion of pure nickel is shown in Fig. 2.

Freezing Point—The freezing point of a pure nickel²⁰ (b) (Fe .024, Cu .016, Co .016, Ni 99.94, C .005) is 1455°C.

Boiling Point—The boiling point of nickel is approximately²¹ 3377°C.

Vapor Pressure—The vapor pressure²² of pure nickel is shown below:

Vapor Pressure, mm. of Hg

Temp. °C.	mm. of Hg	Temp. °C.	mm. of Hg
327	1.315×10^{-23}	1127	2.83×10^{-5}
427	4.92×10^{-19}	1227	2.205×10^{-4}
527	1.493×10^{-15}	1327	1.306×10^{-3}
627	7.26×10^{-12}	1427	6.3×10^{-3}
727	1.005×10^{-10}	1527	2.4×10^{-2}
827	5.55×10^{-9}	1727	2.17×10^{-1}
927	1.552×10^{-7}	1927	1.275
1027	2.57×10^{-6}	2127	5.47

Specific Heat—The true and mean specific heat of a special pure nickel and cobalt free nickel is shown in Fig. 1 and 1A.

Thermal Conductivity—The effect of temperature on thermal conductivity¹⁴ of 99.94% nickel is shown in Fig. 3. The mean¹ (a) value from 0-100°C. is 0.140 cal./sec./sq. cm./°C./cm.

Optical Properties—The reflectivity¹⁰ of highly polished pure nickel (melted and solidified in vacuum) is as follows:

Wave length ¹⁰ of light in microns ($\mu = 0.001$ mm.) ^a	Per Cent
0.25 μ	47.5
0.30	42.0
0.35	45.0
0.40	52.0
0.45	57.5
0.50	62.0
0.55	64.0

Electrical Resistivity—The electrical resistivity of 99.99% nickel is shown in Fig. 4 and is also given in microhm-cm.²² as: R_0 6.141; R_{20} 6.844; and R_{100} 10.327.

The temperature coefficient from 20-100°C. is .00636 per °C.

Electrochemical Equivalent—The electrochemical equivalent of bivalent nickel, using an atomic weight of 58.69, is .0304 mg. per coulomb.

Electrolytic Solution Potential—The single potential of nickel at 25°C. is -0.231 volts (a) on the hydrogen scale.⁹

Thermoelectromotive Force—The thermal electromotive force of nickel against Ag, Pt, Cu and Pb is shown in Fig. 5.

The electromotive force developed is such that the current flows at 0°C. junction from the Ag, Cu or Pt to the Ni, when the emf. is +.

Magnetic Properties—Nickel exhibits no phase transformations. The metal is ferromagnetic below about 360°C. and paramagnetic above that temperature. This magnetic transformation is not accompanied by any change in crystal structure. The temperature of the magnetic transformation is affected by the composition. It is lowered by elements such as copper, carbon, silicon and manganese, up to their limit of solid solubility. This transformation is raised by iron and cobalt.

Physical Properties—The physical properties of unfused electrolytic 99.99% nickel wire, .063 in. dia.¹⁴ (a), hydrogen annealed at >2000°F. for 28 hr., cold drawn 50% and annealed at approximately 1400°F. for $\frac{1}{2}$ hr., are as follows: Proportional

limit, 4,500 psi.; yield stress 0.1% offset, 7,500 psi.; yield stress 0.2% offset, 8,500 psi.; tensile strength, 46,000 psi., and elongation in 2 in., 28%.

Hardness—99.99% nickel,¹⁴ as electrodeposited, has a hardness of 282 Vickers. As annealed in H, for $\frac{1}{2}$ hr. at 1470°F., it has a hardness of 92 Vickers. As annealed in H, for 28 hr. at 2000°F., it has a hardness of 64 Vickers.

Properties of Commercially Pure Wrought "A" Nickel

By G. F. Geiger*

Composition—Commercially wrought nickel has a purity of approximately 99.40%, including cobalt. The following composition is typical: nickel plus cobalt 99.40, carbon 0.10, silicon 0.05, sulphur 0.005, copper 0.10, iron 0.15, manganese 0.20.

Metallographic Structure—The metallographic structure of nickel is typical of that of pure metals. When annealed, it shows a simple polyhedral crystal structure; the grain size of which depends upon the previous thermal and deformation treatment. When annealed after cold working, the metal twins readily and twinning is a prominent microstructural feature of many of the commercially available forms of wrought nickel.

Density—The density¹ (b) of nickel in the wrought form is 8.85 g. per cc. The weight per cubic inch used in commercial calculations is 0.319 lb.

Melting Point—The melting point² of commercial nickel (approximately 99.40%) is 2615-2635°F.

Latent Heat of Fusion—The latent heat of fusion of nickel³ is (a) 73 cal. per g. (131.4 B.t.u. per lb.).

Specific Heat—The mean (a) specific heat⁴ values for commercial nickel are:

Temperature Range, °C.	Specific Heat, cal. per g.
20-300	0.112
20-420	0.118
20-1000	0.126
20-melt. point	0.134

Electrical Resistivity—The electrical resistivity of "A" nickel and electrolytic nickel at different temperatures is shown in Fig. 1. The electrical resistivity of commercial nickel¹ (b) is 9.40 microhm-cm. at 20°C. The temperature coefficient from 20-100°C. determined on the same material is 0.00474 per °C.

Curves showing the resistivity temperature relation for various types of nickel are given in reference 24.

Thermal Conductivity—The thermal conductivity of commercial nickel expressed in watts cm.⁻¹ deg.⁻¹ as determined by S. M. Shelton and W. H. Swanger is as follows:

	Temperature, °C.				
	100	200	300	400	500
Thermal conductivity ⁵	0.828	0.732	0.638	0.593	0.621

*1 watt cm.⁻¹ deg.⁻¹ = 0.239 cal./sec./sq. cm./°C./cm.
 1 watt cm.⁻¹ deg.⁻¹ = 57.9 B.t.u./hr./sq. ft./°F./ft.

Thermal Expansivity⁶—The thermal expansivity of commercial nickel from 25-100°C. is 0.000013. (80-212°F. is 0.0000072.)

Tensile Properties—The average tensile properties of hot rolled and cold drawn "A" nickel rods are given in Fig. 2, and the average tensile properties of "A" nickel sheet and strip are given in Fig. 3.

Effect of Temperature⁷—Slight oxidation starts at approximately 575°F. At higher temperatures, a thin tenacious oxide film forms which permits, in some applications, the use of nickel at temperatures up to 2300°F.

The strength of hot rolled nickel increases with decrease in temperature. The

Nickel	Compression	Tension		Hardness			
	Yield Strength 0.2% offset, psi.	Yield Strength 0.2% offset, psi.	Tensile Strength, psi.	Elongation % in 2 in.	Brinell 3000 kg.	Vickers 30p	Rockwell B
Hot rolled	23,150	24,000	71,000	44.5	107	116	89
Cold drawn 24% and stress relief annealed	58,350	62,000	86,650	33.0	177	190	80
Cold drawn and annealed 3 hr. at 1350°F.	26,200	26,650	73,250	46.0	109	115	49

Torsion—An important property of commercial nickel is the extremely large angle of twist before fracture occurs. The torsional properties¹⁴ of cold drawn commercial nickel tested in the full size rods are as follows:

	1½ in. diameter	1 in. diameter
Proportional limit, psi.....	47,800	52,700
Johnson's apparent elastic limit, psi.....	63,000	61,600
Ultimate strength, psi.....	81,400	
Angle of twist, deg./in.....	341	
Shear twist, in./in.....	2.97	

Impact¹⁴—Impact values are as follows:

Condition	Izod., ft.-lb.	Charpy Tension, ft.-lb.	Charpy Torsion, ft.-lb.	Charpy Impact, 45° V Notch, ft.-lb. —Temperature, °F.—		
				70	-112	-310
Hot rolled	120	29	98	195	236	227
Cold drawn 24% stress relief annealed	120	35	88	190	236	208
Cold drawn annealed 3 hr. at 1350°F.	120	29	113	216	236	234

Modulus of Elasticity—The moduli of elasticity of commercial nickel in tension is 30,000,000 and in torsion 11,000,000.

The variation in moduli due to cold working is insignificant; however, changes of temperature may have a marked effect.

Hardness¹⁴—The hardness ranges for the various tempers are as follows:

Temper	Rockwell B
Dead soft	Under 58
Soft	58-64
Skin hard	65-70
¼ hard	71-79
½ hard	80-85
¾ hard	86-91
Hard	92-98
Full hard	Over 98

Endurance Limit—The endurance limit for nickel depends upon the state of the material. The following figures expressed in psi. were obtained on the rotating cantilever type of machine at 100,000,000 cycles.¹⁴ Annealed 30,000, hot rolled 33,000, and cold worked 50,000.

Pouring Range—In the production of nickel ingots, the metal is teemed in the range of 2800-2890°F.

Heating—Nickel and high nickel alloys should be placed in a hot furnace and removed on a rising temperature. The atmosphere should be maintained reducing and should be as low as possible in sulphur content.

Forging and Hot Rolling—The recommended temperature range for hot working nickel is 2300-1200°F. As the temperature falls the percentage reduction should be decreased. Work below 1200°F. should be considered as cold work. The best hot bending range is between 2250-1900°F.

Cold Working—The cold rolling or drawing of nickel is, in many respects, similar to that of steel. In cold rolling, hardened steel rolls are used and in cold drawing, hardened steel dies and mandrels chromium plated and highly polished are used. While cold rolling is usually carried out dry, lubricants, such as water soluble or oil soluble types, are used in cold drawing operations. Regardless of the type of lubricant, it should be thoroughly removed before annealing.

Annealing—Small parts may be annealed in regular annealing boxes. A reducing atmosphere should be maintained within the box. When open annealed, a reducing atmosphere should be maintained within the furnace and to facilitate pickling, the work should be quenched directly from the furnace in a 2% denatured alcohol water solution. If an oxide film is not objectionable, the work may be water quenched or air cooled. The annealing temperatures are as follows:

	For Softening, °F.	Time at Tempera- ture	Stress Relief		Time, hr.
			For Highly Stressed Material, °F.	For Low Stressed Material, °F.	
Open	1250-1350	2-6 hr.	650-700	900-1000	1-2
Box or closed	1500-1700	15-1 min.	650-700	900-1000	1-2

Machining—The machining of commercial nickel is covered in the article under "Machining the High Nickel Alloys."

Pickling—The type of pickle required will depend upon the previous heating and cooling operations and the desired finish.

1. White surface free from oxide.

a. Bright annealed white metal requiring removal of tarnish by flash pickle.

b. Bright annealed metal requiring the removal of a layer of reduced metal, followed possibly, by flash pickle to brighten.

Flash Pickle—

Water	1 gal.
Sulphuric acid 68° Baumé.....	1½ gal.
Nitric acid 38° Baumé.....	2¼ gal.
Allow to cool for several hours and then add—	
Common salt	¼ lb.

The parts should be dipped in warm water and then immersed in the pickle for 5-20 sec. This should be followed by a hot or cold water rinse, a neutralizing dip in dilute ammonia and washed in hot water.

Pickle for Bright Annealed Nickel—

Water	7 gal.
Sulphuric acid 60° Baumé.....	5 qt.
Sodium nitrate, crude.....	7.5 lb.
Sodium chloride, commercial.....	7 lb.
Add water to make.....	10 gal.
Acidity at start, 15-18%; when dumped, 3½ to 4%.	
Baumé at start, 8°; when dumped, 25-30°.	
Temperature	180-190°F.
Time	20-60 minutes

2. Green or dark colored surface requiring removal of adherent oxide film.

Pickle for Removing Oxide Film from Nickel—

Hydrochloric acid 30° Baumé.....	1 gal.
Water	2 gal.
Cupric chloride	½ lb.
Temperature	180°F.
Time	1 to 2 hr.

Grinding, Polishing and Buffing—The grinding, polishing and buffing of commercial nickel is covered in the section under "Grinding, Polishing and Buffing High Nickel Alloys."

Welding and Soldering—All the welding methods commonly used may be used on nickel. These include oxy-acetylene, metallic and carbon arc, flash, spot and atomic hydrogen welding. This subject, including silver soldering and soft soldering, is covered in detail in a separate article.

Available Forms—Nickel is produced in the usual wrought forms—sheet, plate, strip, tubing, rod, wire and other shapes. These are produced by the usual hot rolling, cold rolling, and cold drawing processes.

Corrosion Resistance—Nickel does not readily discharge hydrogen from any of the common acids. A supply of some oxidizing agent, such as dissolved air, is necessary in order for corrosion to proceed. Reducing conditions usually retard corrosion of nickel, while oxidizing conditions accelerate corrosion. However, nickel has the ability to protect itself against certain forms of attack by development of a corrosion resisting, or passive, oxide film, and, consequently, oxidizing conditions do not invariably accelerate corrosion.

Atmospheric Corrosion—In indoor exposure of nickel there is practically no attack while outdoors the rate of corrosion varies with atmospheric conditions, being usually at rates less than 0.0001 and never more than 0.001 ipy.* Sulphurous atmospheres are most corrosive. Marine atmospheres are scarcely more corrosive than suburban or rural atmospheres. Nickel is free from season cracking and other forms of stress corrosion in atmospheric exposure.

Waters—Nickel is highly resistant to corrosion by waters such as distilled water,

*Ipy means the depth in inches to which uniform corrosion would penetrate during continuous exposure for one year.

natural waters including those containing hydrogen sulphide or free carbon dioxide, and sea water. In the case of sea water, conditions of agitation or flow are favorable to nickel whereas local attack may occur under barnacles or other attached weeds in stagnant exposure.

Salt Solutions—Nickel resists corrosion by neutral and alkaline salt solutions with rates usually less than 0.005 ipy. Nonoxidizing acid salts are only moderately corrosive with rates seldom over 0.02 ipy. Oxidizing acid salts such as ferric chloride and mixtures of oxidizing salts with mineral acids are likely to be severely corrosive to nickel. This is also the case with oxidizing alkaline salts such as hypochlorites with which nickel should not be used where the available chlorine content exceeds 3 grams per litre. Alkaline solutions containing hydrogen peroxide are not corrosive to nickel and are not decomposed by it.

Mineral Acids—Nickel is fairly resistant to sulphuric acid in concentrations under 80%. Corrosion rates vary from less than 0.005 ipy. in air free to about 0.05 ipy. in air saturated and at atmospheric temperatures. In the presence of oils such as in sulphonation processes, nickel is used successfully with sulphuric acid in concentrations over 80%. Nickel is rarely useful in contact with hot sulphuric acid solutions in concentrations over about 15%.

With hydrochloric (muriatic) acid the rates of attack vary with the air content and concentration of the acid from 0.01 to 0.03 ipy. in dilute acid to 0.06 to 0.25 ipy. in concentrated acid. In hot acid, nickel is rarely useful in handling concentrations over about 2%.

Nickel is not corroded appreciably by chlorinated solvents or mixtures of these with water.

It is resistant to pure phosphoric acid, but is corroded severely by this acid when it contains oxidizing impurities such as ferric compounds.

Sulphurous acid is highly corrosive to nickel except in the case of the very dilute solutions used to preserve foods.

Strongly oxidizing acids, such as nitric, corrode nickel rapidly.

Organic Acids and Compounds—Organic acids are only moderately corrosive to nickel while neutral and alkaline organic compounds have practically no effect.

Alkalies—Nickel is resistant to corrosion by the strongest alkalies. For example, in boiling 50% caustic soda, rates of corrosion are less than 0.001 ipy., and in concentrations over 75%, nickel is second only to silver in resisting attack. Anhydrous ammonia is not corrosive to nickel, but ammonium hydroxide is appreciably corrosive in concentrations over about 1%.

Wet and Dry Gases—No dry gases are actively corrosive to nickel at atmospheric temperature. Nitric oxides, chlorine and other halogens, sulphur dioxide, and ammonia are appreciably corrosive when mixed with water or condensed water vapor. Nickel is resistant to chlorine and hydrogen chloride at temperatures up to about 1000°F.

It is not affected by steam within the range of temperatures and pressures commonly encountered.

Nickel resists scaling in oxidizing atmospheres up to about 1400°F. and is also especially useful in the temperature range from 2100-2300°F.

Nickel is not resistant to mixtures of nitrogen, hydrogen, and ammonia in ammonia synthesis process, but is useful in connection with nitriding equipment when the temperature does not exceed about 1075°F.

At temperatures above 600-700°F., nickel may be attacked by sulphur compounds and gases. Under reducing conditions at temperatures above 1190°F., intergranular sulphur attack will occur. In oxidizing atmospheres, sulphidization increases up to 1800°F., above which temperature it decreases considerably. The addition of about 4% manganese improves the resistance of nickel to sulphur attack.

Properties of Cast Nickel

By C. A. Crawford*

Nickel castings are available from foundries specializing in the production of high nickel alloys. Small amounts of carbon, silicon, manganese, and a trace of magnesium are intentionally added to yield sound, ductile castings. Sulphur must be kept low. Lead, tin, and zinc should be excluded. The composition of nickel castings is as follows: Ni 97, C 0.25, Si 1.25, Mn 0.50, Fe 0.50, S 0.01 max., Pb nil, 0.1% magnesium is added at the end of the melt.

General Properties and Uses—Nickel castings are used with rolled forms in the fabrication of equipment used in the process industries, such as the manufacture of caustic soda, artificial silk, photographic film, chemicals, pharmaceuticals, dyes, salts, food products, milk, wines, liquors and soap. They are used in valves, pipe fittings, agitator blades, particularly where contamination with copper or iron must be avoided.

Cast nickel is comparable with other forms of nickel in corrosion resistance. It is highly resistant to such corrosives as atmosphere (industrial, marine and rural), fresh water, salt water, neutral and alkaline salts, acid salts and caustic alkalis. Cast nickel is satisfactorily resistant to mineral acids and organic acids. Nickel is not resistant to oxidizing agents, such as nitric acid, ferric chloride, sodium or calcium hypochlorite and wet chlorine.

For more detailed discussion of the corrosion resistant properties of nickel, see the article on Properties of Nickel.

Physical Properties—The physical properties of cast nickel are as follows:

Ultimate tensile strength, psi. (average) ¹	55,000
Yield strength, .3% offset, psi. (average).....	21,000
Elongation, % in 2 in. (average).....	22
Brinell hardness, 10 mm. ball—3000 kg. load.....	120
Rockwell B hardness, $\frac{1}{16}$ in. ball—100 kg. load.....	67
Charpy impact resistance, ft.-lb. (approx.).....	60
Modulus of elasticity (approx.).....	30,000,000
Specific gravity (approx.).....	8.85
Weight per cu. in., lbs. (approx.).....	0.319
Pattern maker's shrinkage, in. per ft.....	$\frac{1}{4}$
Solidification range, °F. (approx.).....	2550-2650
Electrical resistivity ohms/mil ft. at 20°C.....	134

Properties of Wrought 62% Nickel-15% Chromium Alloy

By F. E. Bash*

General—This alloy is utilized for its electrical properties and resistance to oxidation at high temperatures. Some of its applications are as follows:

Heat Resistant—Elements for heating devices such as toasters, percolators, waffle irons, flat irons, ironing machines, heater pads, hair driers, permanent waving equipment, hot water heaters; sheet carburizing and annealing containers.

Electrical—High resistance, radio and motion picture rheostats; oxidized wire with high resistance coating for close wound rheostats; potentiometers; thermo-couples.

Corrosion Resistant—Dipping baskets for acid pickling and cyanide hardening; automatic pickling machine parts; filter cloth; enameling racks; containers for molten salts.

Physical and Mechanical Properties

Reduction in area, %	47 43 29 18.5 40 57

Resistivity—The electrical resistivity of this alloy as given above, is the highest of any of the nickel-chromium-iron compositions. Its resistivity at room temperature depends on the rate of cooling from temperatures in excess of 1000°F. The rapidly cooled material will have a specific resistance of approximately 3% lower than that which has been slowly cooled.

Temperature Coefficient—The temperature coefficient of resistivity is given in Fig. 1. Two curves are shown. These show the increase in resistance with increase in temperature for material annealed in different manners. The maximum is for material which has been quenched and the minimum is for material which has been slowly cooled.

Oxidation Resistance—This alloy, in common with other nickel-chromium and nickel-chromium-iron compositions, develops a tightly adherent coat of oxide, which protects it against further oxidation. This nickel-chromium oxide will flux with silicates such as sodium, potassium and asbestos and oxides (lead and zinc oxides) at high temperatures, which causes oxidation attack on the metal.

The alloy is in general resistant to corrosion where the media are of an oxidizing nature.

Fig. 1—Temperature resistance curves.

1,800.....	5,000.....		240-600
2,000.....	3,000.....		100-300

Resistance to Corrosion—Resistance and heating elements of this alloy are not subject to corrosion when used in salt water districts nor when exposed to most fumes and chemicals usually encountered in heating processes. This alloy is susceptible at high temperatures to corrosion by sulphur bearing atmospheres, especially when such atmospheres are reducing.

Temperature vs. Electrical Resistivity—The effect of temperature on the electrical resistivity is not a straight line relation and a coefficient of electrical resistivity may not be applied. Fig. 1 shows the average relation for all sizes of wires. The curve may be used for estimating the hot resistance, but for arriving at an accurate figure in design of heating elements or resistances, an actual test should be made on a complete element under operating conditions.

Fig. 1—Temperature vs. resistance for 80% nickel-20% chromium alloy.

Welding—The alloy can be welded by any of the commonly used methods. When oxy-acetylene is used the weld should be made with a slightly reducing flame. A flux of fluorspar is preferable although borax may be used. Welds can be made without flux if the surfaces are not oxidized. If a filler rod is used it should be of the same material. In case a metallic arc method is used the filler rod should be of the coated type developed for this alloy.

* Chief Engineer, Hoekins Mfg. Co., Detroit.

The Properties of Wrought High Nickel-Copper Alloy†

By W. F. Burchfield*

Composition and Physical Constants—Table I gives the composition for this high nickel-copper alloy and the Navy specification, and Table II the physical constants

Table I
Chemical Composition

Element	Typical Composition, %	Navy Specification 46M7 (INT) For Nickel-Copper Alloy Composition, %
Nickel	67.00	63.00-70.00
Copper	30.00	Balance
Iron	1.4	2.5 max.
Aluminum	0.5 max.
Manganese	1.0	2.0 max.
Carbon	0.15	0.3 max.
Silicon	0.1	0.5 max.
Sulphur	0.02 max.

Table II
Physical Constants

Density { g. per cu. cm.	8.80
lb. per cu. in.	0.318
Melting point, °F.	2370-2460

{Torsion, psi.	9,500,000
Poisson's ratio32
Magnetic transformation, °F.	80-203

The magnetic transformation point is affected considerably by slight variations in composition and by mechanical and thermal treatment.

Mechanical Properties—Fig. 1 gives the tensile properties of the alloy compared with the Rockwell hardness.

Table III gives the mechanical properties. The ductility of spring wire is sufficient to allow a bend around its own diameter without fracture.

Sheet or strip has a somewhat greater capacity for bending at right angles to the direction of rolling than parallel to the direction of rolling. Results from the Olsen ductility tests are given in Table IV.

Torsional Strength—The torsional values for the alloy in hot rolled and cold drawn condition are given in Table V. In cold drawn rods, hardness gradient makes the measurement of torsional yield strength by the usual method unsatisfactory. Therefore, Johnson's apparent elastic limit is given as being the most useful engineering approximation.

Endurance and Corrosion Fatigue—The endurance limit in the annealed condition, tested in air, is 37,000 psi. When cold worked the endurance limit is as high

Fig. 1—Average tensile properties of high nickel-copper alloy.

†Trade name "B" Monel.

as 52,000 psi. This alloy retains a high degree of resistance to fatigue even under corrosive conditions. For example, McAdam found the corrosion fatigue limit in brackish water to be 30,000 psi,* as compared with 8,000 psi. for carbon steel under the same condition.

Toughness—Izod values for hot rolled material range from 100 ft.-lb. to the limits of the 120 ft.-lb. Izod machine. Annealed material has an Izod value of about 90 ft.-lb. and material with as much as 50% cold reduction 65-80 ft.-lb., as shown in Fig. 2.

Compression Strength—Table VI shows compression data with the corresponding tensile, hardness and impact data all obtained from the same rods.

Shear—Table VII contains shear strength values for cold rolled sheet or strip, compared with the tensile strength and Rockwell "B" hardness taken from the same material.

Table VII
Shear Strength of Cold Rolled Sheet or Strip

Temper	Shear Strength, psi.	Tensile Strength, psi.	Rockwell "B" Hardness
Annealed..	49,200	70,000	61
Full Hard.	65,200	116,000	100

Hardness—The mechanical properties and hardness of this nickel-copper alloy are increased only by cold working. It does not respond to hardening by heat treatment.

Fig. 3 shows the work hardening by various percentages of cold reduction obtained by cold rolling strip, as compared with other commercial metals and alloys.

To give various balances between ductility, strength and hardness, cold rolled sheet and strip are furnished in nine different hardness ranges, as shown in Table VIII.

Fig. 2—Relationship between impact and surface hardness.

Fig. 3—Work hardening by various percentages of cold reduction.

Hard	Over 40	Over 97	Over 40	Over 97
Full hard				

Elastic Moduli—Young's modulus of elasticity is 26,000,000 and the torsional modulus is 9,500,000. Variation of moduli with cold worked or hot worked condition is not great enough to be significant. The moduli decrease with an increase in temperature. From room temperature to about 400°F., the decrease is about 1,000,000.

Elevated Temperatures—The data in Table IX are for annealed, hot rolled rod and indicate the change of tensile strength and yield strength as determined by short time tests at various temperatures. Table X gives creep test values on annealed, hot rolled rod.

Table IX
Short Time, High Temperature Properties of Hot Rolled Bars

Temp., °F.	Tensile Strength, psi.	Yield Strength 0.2% Offset, psi.	Elong in 2 In., %
70	84,925	32,900	45.8
800	79,625	26,500	49.5
800	69,085	25,375	51.0
1000	50,450	23,925	27.3
1200	32,050	18,360	32.8
1500	14,575	8,375	49.0

Table X
Creep Value^a

Temp., °F.	Stress to Produce Designated Rate of Creep psi.		
	Rate of Creep 0.01% per 1000 hr.	Rate of Creep 0.1% per 1000 hr.	Rate of Creep 1.00% per 1000 hr.
600	26,000	36,000	46,000
800	19,000	23,500	29,000
1000	1,650	4,300	11,500
1200	1,700

Recrystallization Temperatures—While there is evidence that recrystallization of previously highly stressed high nickel-copper alloy may begin at 800°F., no actual annealing can be expected at temperatures below 1200°F., and even at this temperature the annealing time is too slow to be commercially useful. The greater the amount of previous cold work, the lower will be the recrystallization temperature.

Low Temperatures—The proof stress, yield strength, tensile strength, and hardness of this material, all increase as the temperature is lowered. In spite of the increase in yield strength and tensile strength, the alloy suffers no loss in ductility or impact value.

Fig. 4—Percentage change in properties for high nickel-copper alloys at low temperatures.

Fig. 5—Coefficient of thermal expansion of the high nickel-copper alloy.

Fig. 4 shows the percentage of change of the important physical properties as the temperature drops to that of liquid air. **Fig. 5** shows the coefficient of thermal expansion increases slightly with decrease in temperature for the annealed alloy.

Corrosion Resistance—This alloy is a simple, solid solution alloy, so is free from such types of corrosion as sometimes result from local galvanic effects between phases of multiphase alloys.

The types of corrosive discussed below apply to this alloy as well as special grades of it.

Atmospheric Corrosion—In indoor atmospheres this alloy remains substantially unchanged, the principal effect being a slow fogging. In outdoor atmospheres it remains bright only in rural districts that are free from sulphur gases. In sulphurous atmospheres, it will acquire a brownish or greenish tarnish at a rate which will depend on the sulphur content and humidity of the atmosphere. Even where the rate of tarnishing is greatest, there is no destructive corrosion of the metal as it is free from internal structure weakness, season cracking, or stress corrosion cracking. Weight loss data from atmospheric corrosion test specimens have indicated rates of corrosion of less than 0.0001 in. penetration per year at all test locations.

Fresh Water—This high nickel-copper alloy possesses excellent resistance to corrosion by distilled water and natural water, both hard and soft. In distilled and fresh water, rates of corrosion are less than 0.001 in. penetration per year, and often less than 0.00001 in. under the most severe conditions of temperature, flow, and degree of aeration.

Salt Water—This material finds its greatest usefulness in sea water under conditions involving contact with water at high velocity. Stagnant sea water is less favorable, since local attack may occur under marine organisms or other deposited solids.

Neutral and Alkaline Salts—Neutral and alkaline salts have only a slight corrosive action. Rates of corrosion are usually less than 0.001 and seldom more than 0.005 in. penetration per year. It is highly resistant to sodium and calcium chlorides as used in refrigerating brines.

Acid Salts—The material shows good resistance to acid salt solutions, such as zinc chloride, ammonium sulphate, aluminum sulphate, aluminum chloride, and ammonium chloride.

Oxidizing Acid Salts—It is not highly resistant to most oxidizing acid salts, such as ferric chloride, ferric sulphate, cupric chloride, stannic chloride, mercuric chloride, and silver nitrate. This applies also to acids containing chromates, dichromates and other oxidizing compounds.

Oxidizing Alkaline Salts—Hypochlorites are the only common alkaline salts that are definitely corrosive to this alloy. The limiting concentration of available chlorine that may be handled safely is 3 grams per litre. This material is unaffected by alkaline peroxide bleaching solutions.

Mineral Acids—Good resistance to corrosion is shown by all acids except those of a highly oxidizing character. In nonoxidizing acids corrosion does not proceed in the absence of dissolved oxygen.

In air free sulphuric acid at atmospheric temperature, corrosion of the alloy is practically nil in all concentrations up to about 80%. In air saturated acid, below 80% concentration, maximum corrosion occurs with 5% acid at a rate of about 0.04 in. penetration per year.

In 5% acid saturated with air, the most active temperature is about 185°F. The rate of corrosion is about 0.12 in. penetration per year.

The material may be used successfully for handling boiling sulphuric acid (220°F.) solutions in concentrations up to 20%.

In hydrochloric acid the corrosion increases directly with acid concentration. In cold, air free acid, rates of corrosion range from about 0.005 in 1% acid to about 0.04 in. penetration per year in 30% acid. In cold, air saturated acid the spread in corrosion rates is from about 0.03 in 1% acid to 0.2 in. penetration per year in 30% acid. At temperatures in excess of 120°F. the practical application is confined ordinarily to concentrations of hydrochloric acid under 2%.

This alloy is practically unaffected by hydrofluoric acid and mixtures of hydrofluoric acid and fluorides throughout a wide range of concentration and temperature.

The resistance to phosphoric acid depends principally on the purity of the acid, especially in regard to the presence of such oxidizing impurities as ferric compounds.

This alloy is corroded at a moderate rate by hydrogen sulphide with the formation of a dark tarnish, but gives useful resistance to corrosion by oil well brines containing hydrogen sulphide.

Oxidizing Acids—In nitric acid the safe conditions of use include concentrations under 1% at temperatures under 80°F. and where there is little or no movement of the solution or the metal.

Sulphurous acid and bisulphites may be appreciably corrosive.

Organic Acids and Compounds—The alloy shows good resistance to corrosion by all the common organic acids, and is practically free from corrosion by neutral and alkaline organic compounds, and fruit and other food acids.

Alkalies—This alloy is practically resistant to most alkaline solutions, including concentrated caustic soda solutions at temperatures up to the boiling point. In aqua ammonia, or ammonium hydroxide solutions, the material may be used successfully at concentrations up to 3% NH₃. It is not corroded by anhydrous ammonia.

Wet and Dry Gases—This alloy is corroded appreciably by such gases as chlorine, bromine, sulphur dioxide, nitric oxide, and ammonia in the presence of water or condensed water vapor. It is usefully resistant to the effects of steam through the common operating ranges of temperature and pressure.

It is attacked by mixtures of nitrogen and hydrogen under the conditions encountered in ammonia synthesis.

It may be used without progressive scaling at temperatures up to at least 1000°F.

Hot Working Properties—This alloy requires more power for forging than mild steel. It should be placed in a hot furnace and forging started when the temperature is reached. It should not be held at the forging temperature. Sulphur-free fuel should be used or low sulphur content fuel used with precautions. The combustion of the fuel should be complete before the hot gases strike the metal.

The recommended range of forging temperatures is 2150-1600°F. All heavy forgings should be forged above 1850°F. The hot bending range is 2150-1850°F. Care should be taken not to heat the material above the upper recommended temperature limit.

This high nickel-copper alloy may exhibit red shortness within the temperature range of 1200-1600°F.

Cold Working—The high nickel-copper alloy behaves similarly to mild steel in mechanical cold working, as in cupping, drawing, swaging, die forging, power hammering, bending, and forming. The elastic limit is higher, hence more power is required.

Deep Drawing—The deep drawing practice closely follows that for steel. Lubricants with high film strength, such as tallow, castor oil, or good soluble drawing compounds, should be used. Lubricants containing sulphur or lead should not be used if annealing is necessary. The pieces should be annealed after 35-50% reduction.

Spinning—For spinning, the metal should be laid down on hard chucks using long, powerful strokes. Use roller tools if available. Hand tools should be of hardened high speed steel or hard bronze. Tallow or yellow laundry soap should be used for a lubricant. The work must be annealed frequently and in all cases before the ductility of the metal has been exhausted.

Annealing—Bright annealing is easily accomplished in both box and open annealing. Boxes are carefully luted and gas is admitted during the cooling cycle to prevent the entrance of air. In open annealing, sulphur-free oil should be used in furnaces designed so that combustion takes place before the gases strike the work. A reducing sulphur-free atmosphere is essential. An alcohol quenching bath, in the proportion of 1 gal. of methyl or denatured ethyl alcohol to 50 gal. of water, will reduce the oxide flash that results when the work is brought out into the air and will give a silvery white surface. A pink color after the alcohol quenching indicates oxidation in the furnace and improper heating conditions, or an undue delay in quenching.

Lubricants and other foreign matter should be removed thoroughly before annealing.

Table XI gives the recommended annealing temperatures and time at temperature for open and box annealing.

Table XI
Time and Temperature for Annealing

	Temperature, °F.	Time at Temperature
Open Annealing.....	1600-1650	10-7.5 min.
	1700-1750	5-2 min.
	1800	½ min.
Box Annealing...	1350-1450	2-6 hr.

Machining—For details on machining of high nickel alloys, see page 1679.

Welding—For details on welding, see page 220.

Pickling—In commercial pickling, the oxide is first reduced by heating and cooling in a definitely reducing atmosphere, as described under Annealing. A suitable solution for removing the adherent reduced metal is:

Water	3 qt.
Sulphuric acid (66°Baumé)	30½ oz.
Sodium nitrate (crude)	12 oz.
Sodium chloride	12 oz.

Add the acid to the water, then dissolve the sodium nitrate, then add more water to make 1 gal. The temperature should be 180-190°F. and the time required will be 20-30 min., after which the loosened scale may be removed completely by hand or mechanical scrubbing.

In cases where it is impractical to reduce the oxide, its removal may be accomplished in the following pickling solution:

Water	2 gal.
Hydrochloric (muriatic) acid	1 gal.
Cupric chloride (copper chloride)	½ lb.

Cupric chloride speeds up the pickling, but it may be omitted if not available. The temperature should be 180-190°F. The time required, if cupric chloride be used, will be 20-40 min. The articles should be removed at frequent intervals and scrubbed with pumice stone or fine sand, and returned to the pickling solution. Tarnish remaining after the pickling, is removed in a second solution made up as follows:

Water	1 gal.
Sulphuric acid (66°Baumé)	0.1 gal. (1.5 lb.)
Sodium dichromate	1.1 lb.

The temperature should be 70-100°F. and the time required will be 5-10 min., after which the articles should be rinsed in cold water and then dipped in a dilute solution of ammonia (2½ oz. per gal. of 26°Baumé ammonia).

For bright dipping, clean the work in a solution of: water, 1 gal.; nitric acid (38°Baumé) 1 gal.; common salt, 0.8-1.2 oz. Then rinse in hot water and dip quickly for not over 5 seconds in a solution of: water, 1 gal.; nitric acid (38°Baumé), 1 gal. Rinse and dip in the ammonia solution used for pickling. Dry by dipping in steaming water or by rubbing with sawdust. These solutions for bright dipping are used at room temperature.

Forms Available—This alloy is available in the usual mill forms such as hot rolled plates, sheet and strip, rods, shapes, tubing and pipe, wire, and as forgings, castings.

Properties of Wrought Special High Nickel-Copper Alloy† (Machining Quality)

By W. F. Burchfield*

The composition of this nickel-copper alloy and the Navy specification are given in Table I.

Table I
Composition of Nickel-Copper Alloy

Elements	Typical Composition, %	Navy Specification 46M7 (INT) For Nickel-Copper Alloy (Free Machining) Composition, %
Nickel	67.00	65.00-70.00
Copper	30.00	Balance
Iron	1.7	2.5 max.
Aluminum	0.5 max.
Manganese	1.1	2.0 max.
Carbon	0.1	0.3 max.
Silicon	0.05	0.5 max.
Sulphur	0.035	0.025-0.060

This alloy is produced as cold drawn or hot rolled rods for automatic screw machines where high cutting speeds must be maintained. Free machining qualities are obtained with a sacrifice in toughness and strength. The composition has good ductility at room temperatures, but is hot short over a wide range of temperatures so cannot be subjected to hot heading or forging operations.

The physical constants are practically the same as those shown on page 1655. The mechanical properties are given in Table II.

Properties of Cast High Nickel-Copper Alloy†

By C. A. Crawford*

Composition—The composition of this cast alloy controls the limits of the minor constituents, such as silicon, manganese, carbon, iron and magnesium, and excludes the metals which have a detrimental effect on the physical properties at room and steam temperatures, notably lead. Zinc and tin are excluded from this composition for casting, but tin is used in special nickel-copper-tin alloys of high nickel content. Sulphur should be kept to the lowest possible minimum. Magnesium must be used as a desulphurizer and will be found in small amounts. The approximate composition is as follows: nickel 67%, copper 29%, iron 1.50%, silicon 1.25%, manganese 0.90%, carbon 0.20%, sulphur 0.015% max., and lead nil.

The specifications covering this alloy are the Federal specification QQC-551 and the United States Navy 46M1, both for sand castings.

General Properties and Uses—The castings of this alloy show good resistance to corrosion by many mineral acids and salt solutions. They have high strength at the temperatures of saturated and moderately superheated steam (up to 800°F.) and show good resistance to erosion by wet steam.

The castings are used for pump parts, valve bodies, valve trim and turbine nozzles for water, steam and chemical process service. They are used as fittings in pipe lines, pump liners, laundry and textile machine parts, agitators, conveyor chain, flanges, drains, ejectors, gears, heater jets, nuts, manifolds, nozzles, reels, scrapers, screw conveyors, spiders, spouts, strainers, tank fittings, tie rod clamps, and similar applications.

The physical properties are given in Table I.

Properties of Wrought Nickel-Manganese Alloys

By W. A. Mudge*

General—The nickel-manganese alloys belong essentially to the specialty class of engineering materials. They have good mechanical properties and possess a considerable resistance to corrosion toward most media, comparable to that of pure nickel. The presence of manganese in nickel reduces the susceptibility to attack by sulphur gases and accounts for the use of the alloys where this factor is of particular importance.

Fig. 1—The effect of cold drawing upon the tensile strength and elongation (in 2 in.) of nickel-manganese alloys.

given in Table IV.¹ The 15% manganese-nickel alloy has a specific resistance of 290 ohms per mil-ft. (48.19 microms per cm.), a maximum permeability of 8400 gausses at $H = 0.05$, as compared to 5000 at $H = 0.37$ for grade "A" nickel.² The saturation and transformation temperatures are lowered by manganese, the latter effect being about 33°F. per per cent of manganese.³ Alloys containing more than 20% of manganese have limited hot malleability and are not commercial.

Annealing Treatment—The temperatures for annealing are 1300-1400°F., the higher temperature corresponding to the higher percentage of manganese. Cooling from this temperature may be either slow or rapid as the alloys cannot be hardened by heat treatment.

Wrought Forms—The alloys are produced in the usual wrought forms, such as hot rolled or cold drawn rods, bars, wire, and special shapes. Sheet, strip, and plate can be made if desired. Tubing is not available.

Uses—The principal uses of these alloys are for spark plugs, ignition tubes, dental wires, electrical resistance wires, enameling points.

The most important commercial alloys are those containing 2, 5, and 15% manganese, respectively.

Chemical Composition—The figures in Table I are typical of the chemical analyses. Similar values for pure nickel (grade "A" nickel) are included for comparison.

Mechanical Properties—The tensile and torsional properties of 1 in. dia. hot rolled rods¹ are given in Tables II and III. Fig. 1 shows the effect of cold work upon the strength and ductility of the alloys in wire form.

Other Properties—The alloys are similar to pure nickel in general appearance. Each per cent of manganese reduces the density of nickel (8.88 g. per cc.) by about 0.02 and the melting point (1455°C.) by about 5°C. Some electrical properties of these alloys are

Table I

Properties of Wrought Nickel-Copper-Aluminum Alloy*

By C. A. Crawford*

Composition and Physical Constants—The following composition and physical constants are typical of the nickel-copper-aluminum alloy known as "K" monel.

Typical Composition	%	Specification Limits, %
Nickel	66.00	63.00 min.; 70 max.
Copper	29.00	Remainder

Strength in Double Shear—The double shear strength measurements given below were made with the cutters set with a small clearance (.005 in.). This type of test stimulates the service requirements of pins used in shackles or clevises.

Tension		Double Shear	
Tensile Strength psi.	Elongation, % in 2 in.	Maximum Strength, psi.	Deflection at Max. Strength in inches
97,500	49.0	65,300	0.08
155,600	24.0	98,700	0.05

Mechanical Properties—The mechanical properties are given in Tables I and II.

Spring Properties—Wire can be drawn and heat treated from this alloy to 170,000-200,000 psi. tensile strength. The torsional proportional limit cold drawn and heat treated is about 80,000 psi.

This alloy can be used when springs in large sizes cannot be fabricated wholly by cold process. The springs can be made from soft rod or formed hot and the spring temper developed by heat treatment. In this case the tensile proportional limit and tensile strength will be at least 80,000 and 140,000 psi., respectively, and may be greater depending upon the size of the spring and the amount of cold work developed by the coiling.

Endurance Limit—Measurements of endurance limit in air for rod made on a rotating cantilever fatigue testing machine are given in Table III.

Impact—The impact resistance decreases with increasing hardness. Impact values are given in Table IV.

*The trade name of this alloy is "K" Monel.

*Development and Research Division, International Nickel Co., New York.

Cold drawn	106,000	56
Hot rolled heat treated	151,000	40
Cold drawn heat treated	158,000	26

Magnetic Characteristics—This alloy is nonmagnetic under ordinary working conditions and remains so at subnormal temperatures. Careful measurements of permeability at field strengths from 10-300 gilberts per centimeter has shown the permeability (B/H) at room temperature to be 1.0, the same as air. No measurable difference in magnetic permeability between the soft and fully hardened alloy has been found at temperatures higher than -79°C .

Hot Working—When heating, the flame should not impinge directly on the metal. The fuel should be free from sulphur and a reducing atmosphere maintained.

The furnace may be operated at $2200\text{--}2250^{\circ}\text{F}$. However, the metal should never be allowed to reach this figure, but should be removed on a rising temperature between $2000\text{--}2175^{\circ}\text{F}$. This alloy should not be placed in a cold furnace and brought up to temperature, but should be charged into the hot furnace.

The hot working operation must be stopped when the temperature falls to 1700°F . and if the hot work is not completed, the pieces should be immediately returned to the furnace and reheated to the forging temperature. If the continuation of the hot work is not to follow immediately, the work should be held until the temperature drops to 1450°F . and then immediately quenched in water to which 2% alcohol by volume has been added. Unless this quenching is done, stresses will be set up that may result in surface tears on reheating. This alloy air cooled from 1700°F . and not quenched will be excessively hard for practical cold forming or working later.

Cold Working—The increase in tensile strength with cold work is shown in Fig. 1.

Rod—As cold drawn, the tensile strength will be 100,000-135,000 psi. For strength above 135,000 psi, the material must be heat treated.

Strip—The hardness of strip as cold rolled full hard, will be 25-32 Rockwell C and a tensile strength of 165,000 psi.

Wire—Spring wire as cold drawn (65% reduction) and stress-relief annealed at 525°F . will have a tensile strength of 145,000-175,000 psi.

Softening by Quenching—This treatment is carried out at the mill after cold rolling, forging, or cold drawing and should not be

Fig. 1—Effect of cold work and heat treatment

Fig. 2—Softening by quenching from various temperatures.

Fig. 3—Hardening by increasing the holding time.

repeated before the hardening treatment. If it is desired to soften for machining or for cold working proceed as follows:

Heat to a temperature between $1400\text{--}1450^{\circ}\text{F}$., and quench in water or oil. The alloy will not soften if cooled in air except in sections $\frac{1}{4}$ in. dia. or less. Open heating in a sulphur free reducing atmosphere is preferred to using a box because

of the greater ease of quenching. Water to which 1-2% by volume of denatured alcohol has been added is most commonly used as the quenching medium. The alcohol will partially reduce the film of oxide on the metal.

Hardening by Heat Treatment—Hardening by heat treatment is done by holding the metal for 10-16 hr. at 1080-1100°F. followed by slow cooling in the furnace. Fig. 3 shows how hardness increases with holding time.

Higher hardnesses are obtained by cold working (20-30% reduction) then holding for at least 6 hr. at 1080-1100°F. (980-1000°F. for 50% reduction or over), cool to 800°F. at a controlled rate of 25°F. per hr. Cool from 800°F. in any convenient manner.

When the metal has not been cold worked after quenching it may be hardened by holding 30-60 min. at 1200-1250°F. followed by cooling to 800°F. at a rate of 25°F. per hr.

Machining—This alloy with a 300 Brinell hardness can be machined. See page 1679 for the machining of nickel alloys.

Welding—For details on welding see the article on page 220.

Grinding—When grinding it is important to avoid excessive heating, which will change the hardness. Grinding should be done under water or coolant whenever possible.

Pickling—The pickling procedure on page 1661 is suitable for this alloy.

Corrosion Resistance—The corrosion resistance is comparable to that of Monel in organic acids, alkalis, salts, industrial waters, food products, organic compounds and atmospheric oxidation at normal and elevated temperatures; and is superior in aerated ammonia solutions, and inferior in hot dilute sulphuric acid.

Properties of Cast High Nickel-Copper-Silicon Alloys^{a,b}

By C. A. Crawford*

Composition—The 3% silicon, high nickel-copper alloy has good strength and ductility while the 4% silicon type has higher hardness plus resistance to galling but the ductility is low. The composition is as follows:

Ni	Cu	Si	Fe	Mn	C	S max.	Pb
65.0	29.5	3.0 ^a	1.5	0.5	0.1	0.015	Nil
63.0	30.0	4.0 ^b	2.0	0.5	0.1	0.015	Nil

The 4% silicon type has a hard matrix and a structure of fine silicides.

Machining—High speed steel tools are employed for machining the 3% silicon type, but carbide tools are more suitable for the 4% silicon alloy.

Heat Treatment—These alloys are annealed by heating to 1600°F., air cooled to 1200°F., and quenched in oil. The finished work may then be rehardened by heating at 1100°F. for four hours, furnace or air cool.

Hardness—The Brinell hardness of the 4% silicon type in the as cast condition is 330 with 3000 kg. load, 10 mm. ball; after annealing it is 240 and after rehardening 360.

Properties and Uses—The 3% silicon type is used for cast turbine nozzles and steam outlets or in rotating parts where the stresses are high. The 4% silicon alloy is used for valve seats and discs, piston valves and sleeves, pump parts, and where resistance to galling and hardness at elevated temperatures are important factors.

The physical properties are given in Table I.

Nickel-Molybdenum-Iron and Nickel-Molybdenum-Chromium-Iron Alloys

By Burnham E. Field*

Molybdenum metal has a high degree of resistance to chemical corrosion, particularly hydrochloric acid. It is, however, difficult to produce this metal in the form of sheet and fabricated apparatus, so it is used in the form of an alloy that will retain as much of the corrosion resistance of the molybdenum as possible.

Nickel-Molybdenum-Iron Alloys—A nickel-base alloy,¹ with approximately 30%

molybdenum, and 5% iron and 65% nickel, can be supplied as castings, forgings, hot rolled bars, strip, plate, sheet, rods, wire, and welded tubing. This alloy can also be machined. It is resistant to hydrochloric acid in any strength at practically all temperatures, and to sulphuric acid up to 60% concentration of boiling acid. Under these conditions the penetration of the acid is not over 0.003 in. per month, as is shown in Table III.

For many applications in which the corrosive conditions are not so severe as to require the use of the alloy described, it can be made more workable by replacing some of the molybdenum with iron. This alloy,² containing approximately 20% molybdenum, 20% iron, and 60% nickel can be forged and rolled somewhat more readily than the alloy with the higher molybdenum content, although it is more

*Manager, Union Carbide and Carbon Research Laboratories, Inc., Niagara Falls, N. Y.

¹"Hastelloy" alloy B.

²"Hastelloy" alloy A.

difficult to work than steel. This alloy resists hydrochloric acid up to 160°F., sulphuric acid of any strength up to 160°F., and 25% sulphuric acid up to the boiling point. Under these conditions, laboratory tests show the alloy to have a penetration rate of not more than 0.004 in. per month. This alloy can also be readily welded and machined. It is available in the same forms as the alloy containing more molybdenum.

High Temperatures—In mechanical properties, these two alloys are comparable in strength and ductility to alloy steels as given in Table II. As they have good toughness, strength, and machining qualities, they are used in the design of chemical plant equipment and for high temperature work.

Austenitic in Nature—These two alloys are similar in structure to austenitic alloys such as the 18-8 chromium-nickel steels. They contain a small proportion of carbides, even when they have been cooled rapidly from a high temperature. Like other austenitic-type alloys, they are appreciably hardened by cold work with an increase in the yield point and ultimate strength, and a corresponding reduction in ductility. The recommended annealing procedure is to heat them to a temperature of between 2100 and 2150°F., hold them at this temperature a short time according to the thickness of the material, and follow by rapid cooling, depending upon the size and shape of the part. This treatment softens the alloys and develops their high corrosion resistance.

*Aerated test.

Chromium Confers Oxidation Resistance—Chromium as an alloying element confers resistance to the oxidizing solution type of corrosion. In another nickel-base alloy,* approximately 15% chromium is substituted for part of the iron in the analysis of the second alloy described. This alloy, containing 15% chromium, 17% molybdenum, 8% iron, and 60% nickel, meets many corrosive conditions. It is available only in castings, as it is not particularly amenable to forging or rolling. It can be welded satisfactorily and can be machined at low speeds. This alloy resists the attack of oxidizing types of solutions, such as wet chlorine gas and ferric chloride. It is used for chlorinating equipment, cast pipe, valves, pumps, agitators and other forms of equipment for handling wet chlorine or hypochlorites.

Toughness—This nickel-molybdenum-chromium-iron alloy has a strength comparable with that of low or medium carbon cast steel, and although its ductility is not as high as that of steel, it has fair toughness, as shown in Table II, for a cast material. This alloy is not excessively hard, but its structure makes machining—and to an even greater degree, rolling, difficult. Its machinability can be improved, however, by annealing for about two hours at 2200-2250°F., and air cooling.

*"Hastelloy" alloy C.

This heat treatment to improve the machinability of the alloy also results in an increase of both ductility and corrosion resistance. Castings of this alloy are capable of being ground to an excellent finish and can be polished to a high luster. This property is important for applications such as valve seating surfaces and shafts or shaft sleeves which operate in packing glands. Sheets of this alloy cannot be rolled commercially in large sizes, but small sheets are available.

Properties—Tables I, II, and III give the physical, mechanical, and chemical properties of these alloys.

Polishing Nickel and Its Alloys for Metallographic Examination

By R. Vines*

When polishing nickel and its alloys, the avoidance of pitting or loss of inclusions is generally important and a higher grade polish is required with nickel alloys than with copper base materials where considerable metal can be removed in etching.

Samples should not be larger than about 1 x 1 in., preferably about $\frac{1}{2}$ x $\frac{1}{2}$ in. Small samples should be mounted in Bakelite, Lucite or clamps. It is also advisable to have the breadth of the sample greater than the height to minimize rocking and rounding of the edges during polishing. The selected specimen is filed or ground on abrasive wheels, using a light pressure to minimize surface distortion, to a roughly plane surface and then ground on a series of increasingly finer grit abrasive paper discs revolving at 300-600 r.p.m. Usually carborundum papers with grit sizes of 180, 240, 320 and 400 are used although some prefer an alumina grit 400 paper. The grinding on each paper should be at 90° to that of the preceding operation and should be continued until all scratches left by the coarser grit are removed.

Dry grinding on the last abrasive disk is the most critical step as the wet polishing time and the pitting tendency is governed by the depth and uniformity of scratches here produced. In order to get the shallowest scratches possible with this paper, it is advisable to use a well worn or a graphited paper for the final dry grinding.

The procedure following dry grinding depends upon the examination desired, that is, the structure or inclusions. In either case the specimen is carefully washed prior to wet polishing. The wet polishing wheels, which should be free from vibration, are preferably run at rather slow speeds of about 300-400 r.p.m.

Structure Polish—The specimen is polished on a wheel covered with a good grade of billiard cloth charged with a water suspension of No. 600 alumina abrasive. Care should be taken to have the wheel wet enough to prevent dragging but excess water increases the tendency to pit and should be avoided. The pitting tendency can also be minimized by continually turning the specimen on its vertical axis or rotating it in a direction opposite to that of the wheel. When all scratches from the preceding wheel have been removed, the specimen is washed and finish polished on a billiard cloth covered wheel moistened with a relevelated alumina settling at a rate of about 1 in. per hour.

Inclusion Polish—The specimen, which has been carefully finished on graphited 400 paper, is washed and polished on a flat crepe silk covered wheel charged with alumina.

Etching Nickel and Its Alloys for Metallographic Examination

By W. A. Mudge*

Nickel, monel metal, and other nickel-copper alloys may be most satisfactorily etched for microscopic examination with nitric acid solutions. The two following

Fig. 1—Cast monel metal etched with the flat solution
Fig. 2—Same, but etched with the electrolytic solution.
Fig. 3—Cold rolled monel metal etched with the flat solution
Fig. 4—Annealed nickel etched with the flat solution.
Fig. 5—Same, but etched with the electrolytic solution

*International Nickel Co., Huntington, W. Va.

solutions which give excellent results with both cast and wrought products are as follows:

Flat Etching Solution

50 cc. of conc. nitric acid
50 cc. of glacial acetic acid

Electrolytic Contrast Etching Solution

10 cc. conc. nitric acid
5 cc. glacial acetic acid
85 cc. water

Use one 1.5 volts dry cell and platinum wires

The time of etching with the flat solution will vary from 5-20 sec., depending upon the nickel content of the alloy and the depth of etch required. The higher nickel content requires the longer time. Dilution with 25-50% of acetone is desirable when the nickel content of the alloy is less than 25%. The electrolytic contrast solution requires 20-60 sec. Over etching will invariably result in deep pitting.

In order to avoid staining, particularly with the flat etch, only clear, white nitric acid should be used. Best results are obtained at room temperatures. It is best to make a fresh solution daily. After etching, the specimen should be thoroughly washed with water and alcohol and dried quickly with a clean air blast. If a few stains are present in the flat etched specimen, they may be removed by wiping with a clean, smooth cloth or cotton. The electrolytic contrast solution will stain less than the flat solution and further cleaning will not be necessary. It is definitely superior to the concentrated hydrochloric acid solution. Good results with heavily cold worked material are obtained only with the flat solution.

Each of these two solutions serves a particular purpose. The flat solution offers the better opportunity for the detection of sonims, flaws, and porosity. The electrolytic contrast solution is more satisfactory for uniformity of grain size.

Typical photomicrographs, at 100 dia. magnification, are given to show the particular advantages of each solution.

Forging Nickel Alloys

By F. P. Huston*

The forging of nickel alloys depends largely upon proper heating, which involves not only the temperature and the time of heating, but also control of the furnace atmosphere, which is accomplished through correct combustion and the use of appropriate fuel.

With the high nickel materials, exposure of the hot metal to sulphurous atmospheres or other sources of sulphur must be avoided. Metal surfaces that have been attacked by sulphur at high temperatures have a distinctly burned appearance and, if the burning is at all severe, the material is weakened mechanically and rendered useless. The most common source of sulphur is the fuel, so care should be taken to avoid the use of fuels containing much of that element.

Fuel oil should be purchased on a specification, limiting its sulphur content to 0.5% max. The heavier oils purchased under such a specification seldom exceed 0.2% sulphur, and the lighter distillates are practically sulphur free.

Natural gas, practically free from sulphur and with high B.t.u. value, is available in many industrial centers. City gas, which usually is very low in sulphur, is used especially in small furnaces for heating small forgings.

Butane and propane are also satisfactory fuels.

The solid fuels are generally unsatisfactory because of the difficulty of providing for proper heating conditions, inflexibility in heat control, and the presence of sulphur in excessive amounts.

Heating Temperature—Nickel and high nickel alloys show important differences among themselves as to proper forging temperatures, particularly in the upper safe heating limits and in tendencies toward red shortness. Fig. 1 shows the approximate temperature ranges for hammer forging, die forging, and bending.

While heating the high nickel materials, the furnace should be maintained at a temperature about 50°F. higher than that at which the work is to be removed, and in no case should it be less than 2000°F.

Time of Heating—It is bad practice to expose nickel and high nickel alloys to combustion gases in a heating furnace for long periods after the pieces have reached a uniform forging temperature. Where a delay in forging is met, the heated pieces should be withdrawn from the furnace and reheated later when operations are to be resumed.

Approximations of the total elapsed time desirable between charging and pulling the materials are given in Fig. 2. If these ranges are observed, there will be little difficulty in forging and bending. However, these metals are stronger and stiffer than steel at forging temperature, so heavier hammer and larger machines may be required.

The Furnace Atmosphere—The furnace atmosphere should be maintained in a slightly reducing condition, with 2% or more of carbon monoxide. There is no upper limit to the permissible amount of carbon monoxide or free carbon that may be present, as nickel and high nickel alloys are not subject to carburization. The

Fig. 1—Approximate temperature ranges for forging and bending operation. A = nickel 70%, chromium 15.00%, manganese 1.00%, iron 10.00%. B = nickel. C = nickel 67%, copper 30%, iron 1.00%, manganese 1.00% and carbon 0.15%.

closer the atmosphere to the neutral condition, the easier it is to maintain the required temperature.

The stack dampers should be wholly or partially closed in order to force the gases out under the furnace door, where the excess of unburned fuel will burn freely. The pressure set up in this manner prevents the entrance of air under the door or through the slot.

Fig. 2—Approximate time required for heating nickel and high nickel alloys. A = nickel 67%, copper 30%, iron 1.4%, manganese 1.0%, and carbon 0.15%. B = nickel 79.5%, chromium 13%, manganese 1.00%, and iron 6.5%.

cooling, through 180° flat on itself. There will be no sign of cracking if the conditions of heating have been correct. The extent of damage that may have occurred is judged by the depth of the cracks.

To determine correct forging temperature several test bars 1 x ½ x 6 in. are charged into the furnace and a single bar pulled at various temperatures. Each bar is then bent immediately through a 180° bend. The work must be done as rapidly as possible to avoid an excessive drop in temperature while the piece is being bent. When the forging temperature is correct, there will be no sign of cracking at the sharp corners.

Forging Dies—The choice between carbon and alloy steel die blocks for drop forgings and pressings depends largely on the shape and size of the piece, the quantity to be produced, and the material. Dies of 0.80% carbon steel, hardened and tempered to 60 Scleroscope, can be expected to give a good life on the smaller forgings.

Alloy steel dies are necessary for the larger or more intricate shapes and for all forgings in the high nickel-chromium alloy except small, simple shapes.

Trimmer dies should be made of high speed steel, with the cutting edge ground to a considerable rake. They should be set up closely enough to cut tissue paper. The trimming may be done either hot or cold.

It is important that combustion take place before the mixture of fuel and air comes in contact with the metal. If the combustion and heating are both done in the space above the furnace hearth, it is necessary to protect the work by shielding it with steel plates placed so as to prevent the unburned fuel from coming in contact with the hot nickel metal.

Checking Heating Conditions and Forging Temperatures—Before charging the stock in the furnace, it is advisable to check the heating conditions. A test can be made by heating a bar ½ in. dia. or ½ x 1 in. flat, to the required temperature and holding it in the furnace for 10 to 15 min. at temperature. The piece is then either water quenched or air cooled and bent, after

Machining the High Nickel Alloys

By W. F. Burchfield*

Cutting Materials—For general machining of nickel and its alloys, high speed steels of the 18-4-1 type, with 0.70-0.75% carbon content are the most satisfactory. For light cuts and high speed machining, the high speed steels containing cobalt and molybdenum are preferable.

Improved cutting materials, such as the cemented carbide, when used under proper conditions, will prove superior to the high speed steels.

Tool Angles—Tools for cutting high nickel-copper (67-30%) alloys and nickel differ from those properly ground for cutting mild steel only in that a slightly larger true rake angle back from the cutting edge, is required. This holds true for all types of cutting tools.

When machining hard, high nickel-copper alloys, the clearance angle should be kept at a minimum. On heavy, rough machining it is highly advantageous to grind a small land approximately $\frac{1}{2}$ in. wide at the cutting edge, as shown in Fig. 1 and 2.

Lubricants—Though rough turning, rough planing and shaping may be done dry, it is essential to use a cutting oil for all other cutting operations. The correct use of a good cutting oil increases the machining speed about 25% and results in a smoother finish, which is important on machined parts which are to withstand corrosive conditions.

Sulphurized oils give best results. This type of oil may slightly discolor the work but the tarnish is readily removed by soaking the work for 20-30 min. in a cold 10% solution of sodium cyanide.

All lubricants should be thoroughly removed from the machined pieces if they are to be subjected to high temperatures either during subsequent fabrication or in service.

Table I
Recommended Feeds and Speeds for Automatic Screw Machining of High Nickel-Copper Alloys (Free Machining)

Operation	Width of Cut in in.	Feed in in.	Speed in ft. per min.
Box Tool:			
Roughing	$\frac{1}{2}$.006	100-125
	$\frac{3}{8}$.005	100-125
	$\frac{1}{4}$.004	100-125

Straight tool, stock under $\frac{1}{8}$ in dia.0005	100-125
Forming tool.			
Circular	$\frac{1}{8}$ - $\frac{1}{4}$.0006	100-125
	$\frac{3}{8}$ - $\frac{1}{2}$.0005	100-125
	$\frac{5}{8}$ - $\frac{3}{4}$.0004	100-125
	1	.00025	100-125
Balance turning tool			
Turned dia. under $\frac{3}{2}$ in	$\frac{1}{2}$.006	100-125
	$\frac{3}{4}$.005	100-125
over $\frac{3}{2}$ in.	$\frac{1}{4}$.012	100-125
	$\frac{3}{8}$.010	100-125

Turning and Boring—The practical lathe set-up for turning and boring is the same as for mild steel. The only specific instruction is that the cutting edge of the tool be set so that when cutting it is on the center of the work, Fig. 3. Best results are obtained with deep cuts and light feeds.

Roughing tools for turning are shown in Fig. 4, 5 and 6. Fig. 7 and 8 show finishing tools for turning. Lathe tools for machining high nickel-copper (67-30%) castings are shown in Fig. 9, 10 and 11.

Table I gives recommended speeds and feeds for automatic screw machine turning for free machining high nickel-copper alloys.†

*Development and Research Div., International Nickel Co., Inc., New York.

†"R" Monel.

Drilling—Standard twist drills, as furnished by drill manufacturers, have proper angles for drilling high nickel-copper alloys and nickel. See Fig. 12 for recommended drills for drilling these wrought alloys and Fig. 13 for cast high Si-Cu-Ni alloys. Only high speed steel drills should be used, and polished flutes are preferable. For maximum cutting speeds use heavy duty drills for under $\frac{1}{4}$ in. holes, and cobalt high speed drills for the larger sizes. Sulphurized cutting oils give best results. The recommended speeds for nickel and 67% nickel-30% copper alloy are between 40-60 ft. per min. with the same feeds commonly recommended for mild steel.

Fig. 19—Roughing shaper tool for depth of cut up to $\frac{1}{4}$ in.

Fig. 20—Finishing shaper tool for depth of cut up to $\frac{1}{16}$ in.

Reaming—Spiral fluted, high speed steel reamers with narrow lands and well polished flutes, are recommended. Reamers must be kept sharp at all times. Speeds for reaming are approximately 25-35 ft. per min. for nickel and the 67% nickel-30% copper alloy, and lower speeds for some of the special nickel alloys. Reaming feeds are approximately twice the recommended drill feed for the same size hole.

Thread Chasing—Thread chasing should be done with self-opening dies. The dies should have a 15° back rake, as shown in Fig. 14, instead of the usual 7-8° used on dies for steel. A speed of 20-25 ft. per min. is suggested for thread chasing nickel-copper alloy. For free machining nickel-copper alloys, speeds of 25-35 ft. may be employed.

Lathe Threading—Lathe threading is done the same as with any other metal. In cutting 67% nickel-30% copper alloys, the tool should have a back rake angle of 6-9° and a side rake angle of 9-12°, as in Fig. 15. V-threads may be machined in this alloy and nickel at speeds of 25 ft. per min. with light cuts, and Acme or straight threads at approximately 10-15 ft. per min. For other harder nickel alloys it may be necessary to reduce these speeds to 15 ft. per min. for V-threads, and 5-10 ft. per min. for straight or Acme threads.

Tapping—National standard, four-fluted high speed steel plug taps, with ground threads and 7° spiral flutes, or four-fluted, spiral pointed plug taps, are recommended for machine tapping. The plug taps have a four or five thread chamfer. If more chamfer may be tolerated, it is advantageous to extend the taper. The flutes should be ground to give approximately a 15° lip, and the tap should also be "backed off," Fig. 16. On 1¼ in. and larger sizes, the skip thread tap gives excellent results.

The 67% nickel-30% copper alloy and nickel may be tapped at a speed of 20-25 ft. per min. Free machining nickel-copper alloys may be tapped in automatic machines at 25-35 ft. per min.

Planing—The set-up for planing or shaping is no different than for mild steel. Roughing is usually done dry, but for improved surface it is advisable to use a cutting oil for finishing cuts and for parting.

Correct designs of planer tools are shown in Fig. 17 and 18, and for shaper tools in Fig. 19 and 20. Table II lists some feeds, cuts and speeds used on production jobs and will serve as a guide in setting up for planing.

Table II
Feeds and Speeds for Planing
(Heavy Work)

	—Roughing Tool— Fig. 17				—Finishing Tool— Fig. 18			Parting Tool Fig. 2a
Depth of cut, in.	1/8	1/4	3/8	1/2	.020	.015	.010	.005-.010
Feed, in.	3/32	1/8	5/32	3/16	1/16	1/32	3/64
Speed, ft. per min.								
Forged, nickel-copper alloy and nickel	25	25	25	25	25	35	30	30
Forged, unhardened special nickel-copper alloys	15	15	15	15	15	25	20	20

Milling—Milling chips from these materials do not break up into fine shreds or powder but tend to curl. To facilitate the removal of this type of chip, the cutter should be ground with a 10-15° back rake from the cutting edge. Coarse tooth cutters are preferred. Plain or barrel milling cutters should be of the heavy-duty, spiral fluted type. Alternating tooth or interlocking side millers are best for deep holes or for slitting. If only straight tooth milling cutters are available, the sides of the teeth should be cut on a slight taper, widest at the cutting edge. For narrow slotting, high speed steel slitting saws with alternate teeth chamfered, are most satisfactory. This type of circular saw, which is used for cutting copper, is ground concave on the side for clearance.

The surface speed and feed of milling depend a great deal on the strength and rigidity of the milling machine. For general practice, in milling 67% nickel-30% copper alloy and nickel, an average cutting speed of 50-65 ft. per min., with a feed of 0.005-0.010 in. per tooth, depending on the depth of cut, is usually satisfactory. With other harder nickel alloys that have not been heat treated, the surface speed of the cutter must be reduced to around 40 ft. per min. with a feed of from 0.003-0.006 in. per tooth.

Grinding, Polishing and Buffing the High Nickel Alloys

By W. F. Burchfield*

Grinding—Welds—To grind down welds on heavy work on which the finish is unimportant, use either a No. 14 grit or No. 24 grit rubber bond wheel. When finishing light gage work for appearance, a finer wheel, such as No. 36 grit, rubber bond, is preferred.

Rubber or artificial resin bond wheels are desirable for grinding the high nickel alloys.

Avoid overheating the welds in grinding. Excessive grinding wheel heat has been known to cause cracking of welds on thin sheets.

Precision Grinding—Rubber or resinoid bond wheels are superior to vitrified bonded wheels for fine grinding. Silicon carbide abrasive yields the best cutting action and produces the best quality of finish without scratches. The wheels should be soft enough and the grinding conditions sufficiently severe to cause the wheel to yield a slight breaking down action. Always apply an abundance of good lubricant while grinding.

Following are general recommendations for precision grinding: Wheel speed, 4,800-6,000 surface f.p.m.; work speed, 25-50 f.p.m.; table traverse speed for roughing, 80-90, and for finishing, 60-75 in. per min.; feed per pass for roughing, .001-.005, and for finishing, .0025-.001 in.

Polishing (Roll Head Wheels)—This series of operations includes "roughing," "dry fining," "greasing" and "grease coloring"—all accomplished with roll head wheels. Economy is obtained in polishing only by the correct selection of wheels, abrasives, operating speed, and above all, the correct preparation of the wheels.

Artificial abrasives should be used for grits up to No. 150 grit because of their superior cutting characteristics. Turkish emery is preferable for the finer grease wheel finishes and for polishing preparatory to buffing.

In general, there should be from 40-60 grit numbers between successive polishing operations. When preparing a surface for a buff finish, cross the scratches of the preceding coarser wheel, to be assured that the coarser marks are removed.

Buffing (Loose Disc Buff)—Buffing operations performed with loose disc buffs include the "cutting-down" from the polishing scratches preparatory to obtaining a mirror finish by color buffing. The selection of wheels is highly important for buffing. The pocket type buffs, made from high count sheeting, hold the buffing compounds well and are also stiff enough to result in good cutting action. For the highest mirror finish Canton flannel buffs charged with chromic oxide compound, are used.

Tripoli compounds are used for cutting-down operations, and unfused alumina (white) or chromic oxide (green) compounds are used for color buffing. Lime compounds, such as are used for buffing nickel plate, or rouge used for coloring brass, do not have sufficient cutting or coloring characteristics for high nickel alloys and should not be used.

Satin Finish—One method of obtaining a satin finish is to polish with a grease wheel, usually No. 150 or No. 180 grit, and then grease color using a pocket type buff charged with fine emery grease. A second method is to polish first with a grease wheel or rub down the part by hand with No. 180-220 production paper, then brush with a Tampico wheel charged with fine emery grease, or if the area is large and flat, spread a combination of emery flour and oil over the surface and brush with a Tampico wheel.

Another method is by buffing with a pocket type buff charged with a greaseless compound. This compound is a moist mixture of glue and abrasive in stick form, which is charged to a loose disc buff. It is obtainable in several grades. The compounds produce a very pleasing satin finish.

Cleaning—The final operation on all finishing jobs where polishing and buffing compounds have been used, is to sprinkle Venetian lime, "Whiting," over the article, and rub clean with a soft rag. A Canton flannel rag should be used on a mirror finish.

Specific magnetic susceptibility, 18°C.....	1.10×10^{-6}

The physical constants of the platinum metals given in the different sections of this article have drawn freely from earlier compilations.^{1, 2, 3} Where later data have become available, they have been taken into account in selecting the best values for the constants and are discussed below. The atomic weights are from the 1938 value of International Atomic Weights published by the American Chemical Society.

Crystal Structure—The best value for a_0 is that of Owen and Yates⁴ and has been given above. The value given by the International Critical Tables is 3.913 Å.

Density—The density of platinum is given in different places in the International Critical Tables as 21.45, 21.44, 21.46 and 21.5. Owen and Yates⁴ calculated the value of 21.447 at 20°C. The figure of 21.45 consequently represents a good value for the density of platinum.

Melting Point—The melting point is based upon the values of Roeser, Caldwell, and Wensel,⁵ 1773.5°C., Hoffmann and Tingwaldt,⁶ 1773.8°C., and Schofield,⁷ 1773.3°C. A value of 1762°C. was obtained by Ribaud and Mohr.⁸

Boiling Point—This value is based upon the work of Jones, Langmuir, and MacKay.⁹ Mott¹⁰ obtained the much lower value of 4050°C. The International Critical Tables give 4901°C. and 4300°C.

Specific Heat—A value of 0.0318 at 20°C. was obtained by Jaeger, Rosenbohm, and Bottema.¹¹

Linear Coefficient of Expansion—The value of 7.908×10^{-6} is reported by Owen and Yates,⁴ while Shinoda¹² obtained 9.9×10^{-6} from 0-1000°C.

Young's Modulus—These are the values of Grüneisen.¹³ Jacquerod and Mügeli have found the much higher value of 2.82×10^7 for annealed platinum. Purity and physical state may influence this property so much that no decision between the values can be made.

General—Platinum is probably the metal that suffers most from experimenters working with only small quantities. Thus, determinations of the physical constants of platinum are not only few in number, but show a wide variation from observer to observer. Some of the latter trouble probably has been increased further by the use of commercial metal, without consideration of the purity.

Palladium

Atomic weight.....	106.7

Melting point, °C.....	1554
Boiling point, °C.....	about 3800
Specific heat, 20°C., cal. per g. per °C.....	0.0587
Latent heat of fusion, cal. per g.....	36
Linear coefficient of expansion, 0°C., per °C.....	11.60×10^{-6}
Young's modulus, hard.....	1.70×10^7
annealed.....	1.38×10^7

(Continued)

*Physical Department, Baker & Co., Inc., 54 Austin St., Newark, N. J.

Electrical resistivity, 0°C., microhms (cm.)	10.00
Temperature coefficient of electrical resistance, 0-100°C., per °C.	0.00377
Thermal conductivity, 18°C., cal./cm. ² /cm./sec./°C.	0.166
Specific magnetic susceptibility, 18°C.	5.4×10^{-6}

Crystal Structure—The value given above is that of Owen and Yates.⁴ An earlier value by Owen and Iball¹² was given as 3.8850 Å. The best value of earlier work as given by the International Critical Tables is 3.859.

Density—The density of palladium is one of the elusive physical constants. The International Critical Tables list values of 12.0 at 20°C., 12.1 at 0°C., and 12.25. A value of 12.16 has found wide acceptance,^{7, 14} but is probably too high. The different fabricators give various values, mostly below 12.0. Swanger¹⁵ adopted the value of 12.0. Routine determinations of the specific gravity of commercial palladium have been made at Baker and Co. on 33 cast bars of several hundred ounces each. The average for the seventeen most dense bars was found to be 11.99. Owen and Yates⁴ calculated the density from their results as 12.027. Owen and Iball¹² obtained 12.011. Consequently a value of 12.0 seems to be the best value at present.

Melting Point—This constant has been determined by Fairchild, Hoover and Peters¹⁶ as 1553.6°C. ± 5 , and this combined with earlier results led them to adopt a value of 1553.1°C. ± 0.7 . Schofield^{17, 18} made two measurements, obtaining 1555°C. ± 2 , and 1554.4°C. ± 1 . The value of 1554 has been adopted as a good average.

Boiling Point—Two independent determinations have been made by Mott¹⁹ and by Richardson,²⁰ using arc methods. The figure quoted above is the average of their results. The International Critical Tables give the much lower value of 2200°C.

Specific Heat—The value given by the International Critical Tables is 26.2 joules per g. atom, or 0.0587 cal. per g. at 18°C. Jaeger and Rosenbohm²¹ obtained the dependence of the specific heat upon temperature. At 20°C. their results show a value of 0.0543 cal. per g. Later Jaeger and Veenstra²² found 0.0586 at 20°C. Holzman²³ obtained results showing that the specific heat at 20°C. is 0.0587. Poppema and Jaeger²⁴ obtained a formula connecting temperature and specific heat which leads to a value of 0.0586 at 20°C. Consequently the value of 0.0587 continues to be satisfactory.

Coefficient of Linear Expansion—This is the value of the International Critical Tables. A later value of 10.637×10^{-6} per °C. at 20°C. was obtained by Holzman, but this is low compared with most of the other determinations.

General—The affinity of palladium for the gases oxygen and hydrogen makes determinations of the physical properties of palladium itself very difficult. Oxygen tends to cause blistered metal of low density, while hydrogen alloys with the metal, forming the interstitial type of solid solution.

Rhodium

Atomic weight	102.91
Crystal structure	face-centered cubic, $a_0 = 3.7954 \text{ Å}$
Density, 20°C., g. per cc.	12.44
Melting point, °C.	1966
Boiling point, °C.	about 4300
Specific heat, 20°C., cal. per g. per °C.	0.0604
Linear coefficient of expansion, 0°C. per °C.	8.19×10^{-6}
Young's modulus, hard	4.25×10^7
Electrical resistivity, 0°C., microhms (cm.)	4.51
Temperature coefficient of electrical resistance, 0-100°C., per °C.	0.00436
Thermal conductivity 18°C., cal./cm. ² /cm./sec./°C.	0.210
Specific magnetic susceptibility, 18°C.	1.11×10^{-6}

Crystal Structure—This is the value of Owen and Yates.⁴ That of Owen and Iball¹² is in close agreement with it, 3.7954 Å. The figure given in the International Critical Tables is 3.820.

Density—The density is an average of various determinations. Swanger²⁵ obtained an average of 12.41 at 0°C. for vacuum melted rhodium. Rose²⁶ found a value of 12.47 for melted, forged metal. The International Critical Tables give 12.2 and 12.5. In his tabulation of data of rare metals, Swanger²⁵ listed the density of rhodium at 20°C. as 12.46. From X-ray data, Owen and Iball¹² calculated 12.428; and Owen and Yates,⁴ 12.414. In view of the X-ray data, a density of 12.41 would seem a fair value, but higher values have been found, and the figure of 12.44 used by Carter² has been continued.

Melting Point—This is the value of Roeser and Wensel.²² The earlier determination of Wensel, Roeser and Caldwell, as reported by Swanger,²³ led to the value $1985^{\circ}\text{C.} \pm 10^{\circ}$. The International Critical Tables give 1955°C.

Boiling Point—This is the average of the results of Mott² and Richardson,²⁴ 4000°C. and 4500°C. , respectively. The value given by the International Critical Tables is $> 2500^{\circ}\text{C.}$

Specific Heat—This is the average of the figures of Holzman and of Jaeger and Rosenbohm. The International Critical Tables give 0.059 cal. per g. per $^{\circ}\text{C.}$

Linear Coefficient of Expansion—This value is from the International Critical Tables. It is in only fair accord with the later determinations. Swanger,²⁵ obtained 8.3×10^{-6} in the temperature interval, 20 – 100°C. , while the International Critical Tables give 8.59×10^{-6} between 0°C. and 100°C. The results of Holzman seem to be low, being 7.628×10^{-6} at 20°C. A very recent determination by Ebert²⁶ gives the figure 8.5×10^{-6} between 0°C. and 100°C.

Electrical Resistivity—This is Swanger's²⁷ figure. The International Critical Tables give 5.1 in v. I., p. 103 and 4.70 at 0°C. in v. VI., p. 136. Nemlow and Woronow²⁸ give a value 6.02, which seems too high.

Temperature Coefficient of Electrical Resistance—This value is from Swanger.²⁷

Iridium

Atomic weight.....	193.1
Crystal structure.....	face-centered cubic, $a_0 = 3.8312\text{\AA}$
Density, 20°C. , g. per cc.....	22.4
Melting point, $^{\circ}\text{C.}$	2454
Boiling point $^{\circ}\text{C.}$	about 4900
Specific heat, 20°C. , cal. per g.....	0.0309
Linear coefficient of expansion, 0°C. , per $^{\circ}\text{C.}$	6.41×10^{-6}
Young's modulus, hard.....	7.47×10^7
Electrical resistivity, 0°C. , microhms (cm.).....	6.08
Temperature coefficient of electrical resistance, 0 – 100°C. , per $^{\circ}\text{C.}$	0.00392
Thermal conductivity, 18°C. , cal./cm. ² /cm./sec./ $^{\circ}\text{C.}$	0.141
Specific magnetic susceptibility, 18°C.	0.14×10^{-6}

Crystal Structure—The value of a_0 is from Owen and Yates.⁴ Owen and Iball²⁹ give 3.8314. The figure given in the International Critical Tables is 3.823 \AA .

Density—The experimental values are divergent, and the figure above is open to question. Owen and Yates⁴ calculate the density at 22.650, and Owen and Iball²⁹ obtain 22.661.

Melting Point—This is the value of Henning and Wensel,³⁰ who determined it carefully in order to use freezing iridium as a light standard. Their result is 2454°C. A value of 2440°C. was obtained by v. Wartenburg, Werth, and Reusch.³¹

Boiling Point—This is the average of the results of Mott² and Richardson.²⁴ The International Critical Tables give $> 4800^{\circ}\text{C.}$

Specific Heat—This is the value of Jaeger and Rosenbohm.³²

Ruthenium

Atomic weight.....	101.7
Crystal structure.....	hexagonal close-packed, $a = 2.6987\text{\AA}$ $c = 4.2728\text{\AA}$
Density, 20°C. , g. per cc.....	12.2
Melting point, $^{\circ}\text{C.}$	2450
Boiling point, $^{\circ}\text{C.}$	about 4500
Specific heat, 20°C. , cal. per g.....	0.057
Electrical resistivity, 0°C. , microhms (cm.).....	14
Linear coefficient of expansion, 0°C. , per $^{\circ}\text{C.}$	8.51×10^{-6}
Specific magnetic susceptibility, 18°C.	0.50×10^{-6}

Crystal Structure—The lattice constants are from Owen, Pickup, and Roberts.³³ The International Critical Tables give 2.686 \AA and 4.272 \AA .

Density—The value calculated by Owen, Pickup, and Roberts is 12.45 at 18°C.

Boiling Point—This is the average of the results of Mott² and Richardson.²⁴ The International Critical Tables give $> 2700^{\circ}\text{C.}$

Specific Heat—This value is based on the results of Holzman.

Osmium

Atomic weight.....	190.2
Crystal structure.....	hexagonal close-packed, $a = 2.7304\text{\AA}$ $c = 4.3092\text{\AA}$
Density, 20°C., g. per cc.....	22.5
Melting point, °C.....	2700
Boiling point, °C.....	about 5000
Specific heat, 20°C., cal. per g.....	0.031
Linear coefficient of expansion, 0°C., per °C.....	5.70×10^{-6}
Electrical resistivity, 0°C., microhms (cm.).....	9
Temperature coefficient of electrical resistance 0-100°C., per °C.....	0.0042
Specific magnetic susceptibility, 18°C.....	0.05×10^{-6}

Crystal Structure—The figures are from Owen, Pickup, and Roberts. The International Critical Tables give $a = 2.714$ and $c = 4.32$.

Density—Owen, Pickup, and Roberts calculated the density at 18°C. as 22.61 g. per cc. Osmium is traditionally the most dense element; but densities calculated from lattice constants, which are probably more correct for these particular elements, indicate that this distinction should belong to iridium.

Boiling Point—The value is the average of the determinations of Mott¹ and Richardson.¹⁰ The International Critical Tables give $> 5300^\circ\text{C}$.

Specific Heat—This is the value of Jaeger and Rosenbohm.

Properties of Platinum and Platinum Group Metals and Their Alloys

By F. E. Carter* and H. E. Stauss*

Platinum—Four grades of platinum are in common use, although in the United States there is no formal recognition of the fact.¹

In addition the 5 and 10% iridio-platinum alloys are frequently called "medium hard" and "hard" platinum respectively. The grades are shown in Table I. Usually the impurities consist of the other platinum metals, for example, iridium or rhodium, although the commercial metal may contain small quantities of base metals.

Table I
Grades of Platinum

Designation	Platinum, %	Use
Physically pure	99.99	Thermocouples, resistance thermometers
Chemically pure	99.90	Catalysts
Crucible	99.5	Laboratory Ware
Commercial	99.0	General

The properties of platinum vary with the grade, and for scientific purposes only chemically pure platinum should be used, although, in the literature, for the determination of physical properties of alloys, commercial platinum of uncertain purity has frequently been used. The physical properties of chemically pure platinum are given in Table II.²

Table II
Properties of Platinum

Brinell Hardness		Ultimate Tensile Strength, psi.		Erichsen Number		Resistivity,	Temp. Coeff.
Hard	Annld.	Hard	Annld.	Hard	Annld.	ohm/mil. ft. 0°C.	of Resist., 0-100°C.
97	42	34,000	17,000	7.8	12.2	60	.0039

In the use of platinum at elevated temperatures, reduction of the melting point by inadvertent alloying must be guarded against. Platinum should never come in contact with low fusing elements at a high temperature nor with oxides of low fusing elements under reducing conditions. It should preferably be used under oxidizing conditions.

For many purposes pure platinum itself is too soft, and it is used in alloyed form. The additions are usually iridium or rhodium, but in Europe alloys with copper are common. All the other metals of the platinum group as well as a number of base metals are used for hardeners of platinum for special purposes. The hardening effect of various metals on platinum is shown in Fig. 1.

Platinum finds use in many and diverse fields and is absolutely essential in some of them. Mention may be made of its use for catalysts and noncorrosive and high temperature equipment in the chemical industry, spinnerettes for glass fibers and rayon, electrodes, thermocouples, and resistance thermometer elements, furnace windings, general laboratory ware, electrical contact points, dental foil, and, of course, jewelry.

Palladium—This is the only member of the group, other than platinum, which is easily workable and which is used to any extent commercially, in unalloyed form. The physical properties are not greatly different from those of platinum, as shown in Table III.²

Table III
Properties of Palladium

Brinell Hardness		Ultimate Tensile Strength, psi.		Erichsen Number		Resistivity,	Temp. Coeff.
Hard	Annld.	Hard	Annld.	Hard	Annld.	ohm/mil. ft. 0°C.	of Resistance, 0-100°C.

*Physical Department, Baker & Co., Inc., 54 Austin St., Newark, N. J.

Fig. 1.—Hardness of platinum alloys. Influence of additions of other metals upon the baby Brinell hardness of platinum (2 mm. ball, 120 kg. load).

Fig. 2.—Hardness of palladium alloys. Influence of additions of other metals upon the baby Brinell hardness of palladium (2 mm. ball, 120 kg. load).

listed the properties of the alloys as compiled from published^{4,5} and unpublished work. The properties vary with the purity of the components of the alloys as well as with the manner of preparation. Therefore this table, and the following ones for alloys, should be considered as giving good average values of the properties of the alloys rather than as giving exact physical constants. In the case of hardness, not all published figures for Brinell hardness have been made with the same ratio of load to penetrator diameter, and consequently are not comparable. In the tables of

Like platinum, palladium is soft and is frequently hardened by additions of other elements. In Fig. 2 is shown the influence of several elements on the hardness of palladium.

Palladium is used in dentistry, in jewelry, and in electrical contact points; also as a catalyst, as foil for various decorative effects, and for photographic printing paper.

Rhodium—Rhodium can be fabricated only with difficulty, requiring hot working for large sizes, although small sizes can be cold rolled or drawn. The uses of the metal in its pure state are limited, being confined to the production of a nontarnishing electroplate. The physical properties have not been thoroughly studied, but what are known are shown in Table IV.⁶

Table IV
Properties of Rhodium

Brinell Hardness Hard	Resistivity, ohms/mil. ft. 0°C.	Temp. Coeff. of Resistance, 0-100°C.
390	135	.0044

Iridium, Ruthenium, and Osmium—Of these three metals, only the first has been worked so far and even iridium is extremely brittle. Iridium and osmium occur together naturally as the very hard osmiridium. Artificial alloys among these three elements, with or without platinum, are used when extremely hard noble metals are desired, such as penpoints and some electrical contact points; they are, however, too brittle to be worked.

Platinum-Iridium Alloys—The iridium alloys with platinum are the most important with respect to volume of consumption, because they are standard for jewelry. Those most commonly used are the 5 and 10% alloys, the "medium hard" and "hard" platinum of commerce, but alloys containing up to 30% iridium are in regular use for fuse wires, hypodermic needles, and electrical contacts. The important qualities of the alloys are their hardness, their high electrical resistance, and their resistance to corrosion. In Table V are

this article only baby Brinell hardnesses are given, using a two millimeter ball and a load of 120 kilograms.

Table V
Properties of Platinum-Iridium Alloys

% Ir	Brinell Hardness		Ult. Tensile Strength, psi.		Erichsen Number		Resistivity, ohms/ml. ft. 20°C.	Temp. Coeff. Resistance, 10-160°C.
	Hard	Annld.	Hard	Annld.	Hard	Annld.		
5	140	90	70,000	40,000	7.1	10.7	115	.0020
10	185	130	90,000	55,000	7.1	10.4	150	.0013
15	230	160	120,000	75,000	7.0	10.2	170	.0010
20	265	200	145,000	100,000	7.0	9.7	190	.0008
25	310	240	170,000	125,000	4.1	7.8	200	.0006
30	360	280	200,000	160,000	..	2.0	210	.0006

Platinum-Rhodium Alloys—Of recent years these alloys have been assuming importance because of their usefulness at high temperatures. While they are not as hard as the corresponding iridium alloys, they resist to a far greater extent oxidation and the development of intercrystalline weakness at elevated temperatures. In laboratory ware they show greater stability of weight than do iridium alloys and the alloy containing 3½% rhodium is widely used for such articles. The 10% alloy is the most common in technical and chemical applications. The alloy containing 20% rhodium is used to some extent for furnace windings, and other alloys have been employed for special purposes. The properties of the alloys as gathered from the available material^{1, 2, 3, 4} are given in Table VI.

Table VI
Properties of Platinum-Rhodium Alloys

% Rh	Brinell Hardness		Ultimate Tensile Strength, psi.		Erichsen Number Annealed	Resistivity, ohms/ml. ft. 20°C.	Temp. Coeff. Resistance, 25-100°C.
	Hard	Annld.	Hard	Annld.			
3.5	120	60	60,000	25,000	11.8	100	.0022
5	130	70	70,000	30,000	11.7	105	.0020
10	165	90	90,000	45,000	11.2	115	.0018
20	210	120	130,000	70,000	10.4	125	.0014
40	290	150	105	.0014

Because of the importance of the 10% alloy, Table VII is inserted to show its resistivity at elevated temperature and its tensile strength at temperature as compared with that at room temperature, as determined on 0.050 inch wire¹ and on smaller wires (unpublished data).

Table VII
Resistivity and Tensile Strength of Platinum-Rhodium (90-10) at Elevated Temperatures

Temperature, °C.	Resistivity, ohms/ml. ft. 20°C.	Ratio of U.T.S. at temperature to that at 20°C.	
		Wire dia. 0.050 in.	Wire dia. 0.010 in. & 0.003 in.
20	114	1	1
500	203	0.66	0.71
700	236	0.54	0.57
900	267	0.38	0.43
1100	296	0.23	0.29
1300	324	...	0.15
1500	356	...	0.08

Platinum-Palladium Alloys—Palladium is sometimes added to platinum, usually to reduce the cost, the density and price of palladium being the lowest of the group. The properties of the system are shown in Table VIII.^{1, 2}

Table VIII
Properties of Platinum-Palladium Alloys

% Pd	Brinell Hardness		Ultimate Tensile Strength, psi. Annealed	Erichsen Number Annealed	Resistivity, ohms/ml. ft. 20°C.	Temp. Coeff. Resistance, 0-160°C.
	Hard	Annld.				
10	145	80	45,000	11.5	120	.0014
20	175	95	50,000	11.0	150	.0012
30	180	100	52,000	11.0	170	.0010
50	175	100	50,000	11.0	165	.0010
75	150	80	43,000	11.5	130	.0014

Other Platinum Alloys with Noble Metals—Other alloy systems which have been used or studied, although they are not in common commercial use, are given below, with such physical properties as are available.^{2, 4, 5, 11, 12, 16} Ruthenium and osmium harden platinum at a very rapid rate. Gold and silver behave the same way. The last two elements, and probably the first two, have only limited solubility in platinum at room temperature. Gold and platinum form continuous solid solutions at high temperatures, but at low temperatures form conjugate solid solutions, consequently the platinum-gold alloys in the middle of the series are age-hardenable. In commercial use, it has been gold hardened by platinum, rather than platinum hardened by gold, that has been found serviceable.

Table IX
Physical Properties of Alloys of Platinum with Other Precious Metals

20% Ag	...	172	128,000	..	320	.00050

Platinum Alloys with Base Metals—Alloys of platinum with base metals are of interest because of the special properties that may be obtained. When the base metal addition is low, nobility at room temperature is frequently little impaired. The platinum-copper series has long been of interest because of the age hardening property of the alloys.⁹ Platinum-nickel alloys form a continuous series of solid solutions, one of which, the 5% nickel alloy, has been used as the filament in amplifying tubes. The platinum-iron alloys are of interest because of their magnetic properties, alloys containing more than 17% iron being strongly magnetic. The properties of the alloys are shown in Table X.^{2, 5, 9, 10, 11, 12}

Table X
Physical Properties of Platinum Alloys with Base Metals

Alloy	Brinell Hardness Annealed	Ultimate Tensile Strength, psi.		Resistance, ohms/mil. ft. 20°C.	Temp. Coeff. Resistance, 25-100°C.
		Hard	Annealed		
5% Ni	140	103,000	65,000	140	.0020
10% Ni	200	180	.0013
20% Ni	2700009
5% Cu	110	92,000	63,000	227
10% Cu	135	335	.00015
20% Cu	145	540	.00016
5% Fe	700011
10% Fe	950005
20% Fe	1400009

Palladium Alloys—Palladium is used alloyed with gold, silver, or platinum, and of late, alloys using small percentages of ruthenium and rhodium have been developed for use in jewelry. Alloys with the base metals copper or nickel also find use. The silver alloys form a continuous series of ductile alloys, as do the gold alloys; the former are used for electrical contact points, the latter for spinnerettes in the rayon industry. Both ruthenium and rhodium harden palladium rapidly, but the ternary alloys including both are preferred by the jewelry trade as having a better color. Nickel hardens palladium rapidly, apparently forming solid solutions. Copper and palladium are also solid solutions, but show intermetallic compounds and transformations in the solid state at low temperatures, and so are age-hardenable. Unquestionably the most important of all palladium alloys^{13, 14} are those used in dentistry, but these are too complex to be discussed here.

The Use and Care of Platinum Ware—It is important to remember that, although platinum is not oxidized in the air at any temperature, nor attacked by any single

acid, yet there are many substances that attack and combine with it at comparatively low temperature.

The caustic alkalis, the alkaline earths, nitrates and cyanides, and especially the hydroxides of barium and lithium attack platinum at a red heat, although the alkaline carbonates have no effect at the highest temperatures. Phosphorus and arsenic attack platinum when heated with it; therefore phosphates and arsenates should not be ignited in their filter paper in the crucible. Silicon, which may be formed by the reducing action of carbon on silica, causes brittleness. Contact with compounds of easily reducible metals like lead is dangerous at high temperatures, because low fusing platinum alloys are readily formed.

Do not put platinum in the inner cone of the Bunsen flame; the carbon in this cone reacts with the platinum to form a carbide which causes brittleness and general deterioration.

Every careful analyst of necessity uses clean utensils. The habit of cleaning and polishing platinum were immediately after using is easily formed, and repays the user with increased confidence in his work as well as with the prolonged life of the article.

The loosening effect of the Bunsen flame upon the surface of platinum exposed to its action produces the familiar gray appearance which cannot be removed except by burnishing. Rubbing the surface of platinum with moist sea sand (round grains only), applied with the finger, serves to remove most impurities and to polish the metal, without material loss in weight.

Fusing bisulphate of potash or borax in the vessel and then boiling in water and polishing as above with sand is recommended by Gmelin. When it is desired to clean the outer surface of vessels in this manner, they must be placed in dishes of sufficient size to allow the fused flux to envelop completely the article to be cleaned.

Sodium amalgam possesses the property of wetting platinum without amalgamating with it, even when other metals are purposely added to the amalgam. This substance is, therefore, useful for effecting a quick and thorough cleansing of platinum. The amalgam is gently rubbed upon the metal with a cloth and then moistened with water, which oxidizes the sodium and leaves the mercury free to alloy with foreign metals. The mercury is then wiped off and the article cleaned and polished with sand, as above described.

If the existence of a base metal alloyed with the platinum is suspected, immerse the article in question first in boiling hydrochloric acid for a few minutes; then, after thoroughly rinsing with clean water, in boiling nitric acid free from chlorine. If the article is unaffected in weight or appearance, and the acid baths fail to give reaction for base metals, the absence of such is assured.

The Tin Industry

By R. L. Hallett*

Introduction—Tin is almost unique among the important common metals in that nearly the entire production of the world comes from countries in which practically no tin is consumed. This is of particular importance with reference to the United States, which consumes approximately half of all the tin produced in the world but does not recover any appreciable amount from domestic ores. This economic situation is not due to any lack of perspective, technical knowledge, or aggressiveness on the part of American industrialists, but is solely due to the fact that as yet no commercial tin deposits have been found in the United States. This makes the United States dependent on other countries for its tin requirements.

History—Tin was known to the ancients as early as 3000 B. C. and was used by the Phoenicians, Greeks, and Romans long before the Christian era.

The principal use for tin in ancient times was for making bronzes in which tin was added to copper for hardening purposes. The Bronze Age could not have existed without tin and the ability of various peoples to obtain and use tin for making bronze weapons and agricultural implements was a major factor in the progress and dominance of ancient nations.

Tin continues to be an important metal with many important uses and is indispensable in many industries today.

Sources of Tin—The primary source of tin is the natural mineral cassiterite which is the oxide SnO_2 . This mineral, sometimes called "tin stone," is found in many parts of the world but deposits of commercial importance are relatively rare and occur in comparatively few localities. The pure mineral contains about 78.6% tin, but even in the richest commercial deposits the tin mineral is more or less intimately mixed with large amounts of other minerals from which it must be separated.

The valuable tin deposits are of two distinctly different kinds which may be classified, according to their method of formation, as vein or lode deposits and alluvial or placer deposits. In both formations the tin mineral is cassiterite but in the vein deposits the cassiterite occurs as a primary mineral deposited in solid fissure veins, while in the placer deposits the cassiterite is found in separated particles mixed with other minerals in secondary sands and gravels.

The large and important tin mines are located in Malaya, Bolivia, Dutch East Indies, Siam, China, and Nigeria which together account for about 90% of the entire virgin tin annually produced in the world.

In addition to the virgin tin produced from natural mineral deposits a large amount of secondary tin recovered from waste and scrap metal materials comes into the market.

Mining and Metallurgy—The large operating mines of Bolivia are almost entirely vein formations, whereas the mines of Malaya, Dutch East Indies, Siam, China, and Nigeria are largely placer deposits, although formations of both types are found in all of the large production areas.

A great part of the world's tin production comes from vein ores containing from 2-4% of tin and from placer gravels yielding from 1-2 lb. of tin per cu. yd. The tin ore is removed from the vein deposits by usual deep mining methods while the placer gravels are mined by dredging, hydraulic sluicing or more primitive hand methods.

The crude ore from the vein deposits is crushed to liberate the tin mineral from the waste and the crushed ore or placer gravel is treated at the mines by various mechanical methods to remove the waste minerals and concentrate the tin mineral. The crude tin concentrate contains approximately 70% of tin and is shipped to the smelters.

For economic reasons the smelting of the tin ores is largely done in a few large modern smelting plants to which the tin concentrates are shipped from the various mining districts.

*Chief Chemist, National Lead Co., Brooklyn.

Table I
Commercial Brands of Tin*

Company and Brand	Tin %	Antimony %	Arsenic %	Lead %	Blanc %	Copper %	Iron %	Silver %	Cadmium %	Cobalt %	Nickel and Sulphur %

*This table represents average composition of the various brands. Compiled by the author with the assistance of D. J. Macnaughton of the International Tin Research & Development Council from information obtained from producers.

The principal tin smelting and refining plants are as follows:

Consolidated Tin Smelters, Ltd.....	Bootle, England
Consolidated Tin Smelters, Ltd.....	Penang, Straits Settlements
Straits Trading Co., Ltd.....	Singapore, Straits Settlements
Straits Trading Co., Ltd.....	Penang, Straits Settlements
N. V. Hollandsche Metallurgische Bedrijven.....	Arnhem, Holland
Netherlands East Indian Government.....	Banka, Netherlands East Indies
Societe Generale Metallurgique de Hoboken.....	Hoboken, Belgium
Yunan Tin Corporation.....	Kochiu, Yunan, China

Brands and Markets—The different tin smelting and refining companies produce and market tin under various proprietary brand names. A number of the important brands with their composition are given in Table I.

The crude tin from the Yunan Tin Corp. and many smaller Chinese smelters is refined in several refining plants in Hong Kong. The Chinese refined tin is known as Chinese No. 1 and is sold with the guarantee that it contains not less than 99% tin.

The price per pound of Straits tin at New York has varied from a low of 18.35 cents to a high of 71 cents during the ten year period from 1927 to 1937.

Consumption and Uses—The tin consumption of the world has varied from a low of 107,400 long tons to a high of 182,249 long tons during the ten year period from 1927 to 1937, and the consumption of the United States has varied between 40,600 long tons and 87,000 long tons during the same years.

The Minerals Year Book of the United States Bureau of Mines publishes some statistics showing the classification of the various uses of virgin tin consumed in the United States. For the years 1927, 1928 and 1930 the classification was as follows:

Virgin Tin Consumed in the United States

Uses	Average for 1927, 1928 and 1930, % of Total
Tin Plate and Terneplate.....	38.25
Solder	18.68
Bearing Metal	10.14
Bronze	6.00
Foil	5.88
Collapsible Tubes ..	4.55
Chemicals	4.85
Tin Oxide	1.51
Tinning (Other than Tin Plate).....	3.91
White Metal	1.35
Type Metal	0.52
Castings	0.86
Other Alloys	0.71
Miscellaneous	2.79
	100.00

While the consumption of virgin tin in the different industries varies somewhat from year to year, the above three year average figures are fairly representative and indicate the relative importance of tin for various industrial purposes.

Constitution of Tin-Antimony Alloys

By W. A. Cowan* and G. O. Hiers†

The tin-antimony alloys are of commercial importance in type metals, Britannia metal, and Babbitt for lining bearings. Another element is generally added and the tin in such a material is capable of infinite variation, while the antimony seems to be confined to a maximum content of about 25% because of the increased brittleness which it confers.

The tin-antimony system was constitutionally examined 20 years ago and the liquidus and solidus curves fixed with fair accuracy. The transformations in the solid state have not received much experimental attention and the solid solubility lines plotted in Fig. 1 are mostly hypothetical as conceived by Guertler.

The liquidus curve, represented by joining the points EDCBA, irregularly descends from 630°C., the melting point of pure antimony, to 232°C., the melting point of pure tin. Four solid solutions form the constituents that freeze out first in their respective ranges; namely; the delta solid solution, between the compositions of 100 and 50% antimony; the gamma, between 50 and 21% antimony; the beta, between 21 and 9% antimony; and the alpha, between 9 and 0% antimony.

Fig. 1—Tin-Antimony Constitution Diagram

The line F N has been determined by Hanson and Pell-Walpole. The solubility of antimony drops from 10.3% at the peritectic point 246°C. to 4% at 190°C. and then gradually to 3.5% at 0°C.

The solidus curve made by joining the points ELKJHGFA is somewhat complex, due to 3 peritectic reactions at K, H, and F, which are responsible for the temperature horizontals of the solidus at 427, 319, and 246°C. The completely solid alloys consist of either a single solid solution or a mixture of 2 solid solutions, and the solid solubility curves in each case show that the solubilities decrease as the temperature falls.

An explanation of 1 peritectic reaction will serve for all three observed in this system. For instance, alloys between the compositions of 88 and 62% antimony form a mixture of solid solutions gamma plus delta on freezing at 427°C. At the invariant point K there are 3 phases in equilibrium with each other. The liquid metal, however, has an excess of tin over that indicated by K and so the liquidus continues to slope from D to C. The delta solid solution, previously in equilibrium with the liquid metal, changes to the gamma solid solution which is also in equilibrium with liquid metal in the composition range of 62-50% antimony and at 427°C.

At 49% antimony the compound SbSn probably exists and may be considered responsible for the characteristic cubic structure observed in the beta solid solution. The e.m.f. composition measurements made by Puschin show an abrupt change at this point on the curve. He has also suggested the possibility of a second compound, Sb₂Sn, but such a view is not generally maintained.

According to van Klooster and Debacher single crystals of SbSn have a simple

*Asst. Chief Chemist and †Metallurgist, National Lead Co., New York.

This article not revised for this edition.

cubic lattice of the NaCl type, with 4 antimony and 4 tin atoms at the corners of the unit cell. The atomic distance was found to be 3.06' A.

Constitution of Tin-Bismuth Alloys

By W. A. Cowan* and G. O. Hiers†

Binary alloys of tin and bismuth are seldom, if ever, used industrially. These metals are, however, of considerable importance in fusible alloys, which contain in addition either or both lead and cadmium.

The system is essentially of the simple eutectiferous type with the 2 branches of the liquidus AB and CB meeting at the eutectic point, 57% bismuth, and at 135°C. (See Fig. 1.)

From 0-57% bismuth the primary constituent is the alpha solid solution of bismuth in tin and from 57-100% bismuth the primary constituent is the beta solution of tin in bismuth.

The solidus passes through the points ADBEC. Immediately after solidification alloys between 0-6% bismuth consist of the single solid solution alpha, those between

6 and 97% bismuth of a mixture of alpha plus beta solid solutions, and finally those between 97 and 100% bismuth of the single phase beta. The exact shape of the solidus curve AD and CE has not been experimentally defined.

Below the eutectic temperature the tin is less able to keep bismuth in solution and a eutectoid inversion takes place at 95°C. The approximate limits of solid solubility are given by the dotted lines FH and DH. In alloys covering

Fig. 1—Tin-Bismuth Constitution Diagram

a wide range, this transformation can be detected by sensitive cooling curve methods, as shown by the transformation horizontal GHJ. Below 95°C alloys from 0-98% bismuth are duplex in structure and contain pure tin and beta solid solution.

The solubility limit of the beta solution is approximately indicated by the line EJL, although this feature of the diagram has not received much experimental attention.

No phase change is shown in the diagram at 18°C. because bismuth has been shown to be very effective as an inhibitor in the change of beta to alpha tin. (Tin disease-gray tin.) According to G. Tammann and K. L. Dreyer, tin disease is completely suppressed by 0.5% bismuth. In a later investigation, Mason & Forgeng find 0.0035% bismuth is a preventative, provided the bismuth is in homogeneous solid solution. They state that 0.001% bismuth in uniform solution does not inhibit the transformation.

Constitution of Tin-Cadmium Alloys

By W. A. Cowan* and G. O. Hiers†

These metals form a eutectic at 33% cadmium and at 176°C. There are three primary constituents which solidify first in the following ranges: From 0.0-3.8% cadmium, alpha; from 3.8-33% cadmium, beta; and from 33-100% cadmium, gamma.

The liquidus is designated by the line A B C D, while the solidus is obtained by joining the points A E F G H D.

Cadmium in the amount of 1.2% is soluble in tin over a considerable range in temperature, as shown in the area indicated by A E J K, representing the alpha solid solution.

Fig. 1—Tin-Cadmium Constitution Diagram.

L G F denotes the uniphase solid solution beta. The field L M H C G represents the existence of the two solid solutions beta and gamma, while the area indicated by D H M N denotes the solid solution gamma.

The field indicated by K J L M N represents a mixture of the two solid solutions, alpha plus gamma. There is a eutectoid point at 5% cadmium and at 130°C. The eutectoid horizontal J L M exists between 1.3-99.5% cadmium. The transformation of the beta solid solution to the alpha solid solution occurs at this horizontal. Here structural transformation may be associated with the allotropic gamma to beta phase change in pure tin.

At this time, there are no positive data pertaining to the influence of cadmium in respect to the phase change which occurs in pure tin with the allotropic change from the beta to the alpha state.

The data used in plotting this diagram have been principally taken from the investigations of D. Hanson and W. T. Pell-Walpole.

The Constitution of Tin-Copper Alloys

By W. A. Cowan* and G. O. Hiers†

The tin-copper alloys are of such great practical importance in the nonferrous industry and are of such a complex nature that it occasions no surprise to find an extensive record of careful investigation in this field. Heycock and Neville's early work on these alloys has been accepted as one of the classical researches in metallography and it is remarkable how closely their results agree with work performed with modern refinement of apparatus.

The alloys described herewith, containing from 0-50% copper, have been studied thoroughly by J. L. Haughton, who not only reviewed all previous investigations, but in his own work made use of long period annealings which are necessary in order to insure true equilibrium conditions. His diagram has been adopted by the International Critical Tables and is made the basis of this article.

Fig. 1—Tin-rich portion of the tin-copper constitution diagram.

a uniphase solid solution, epsilon. The field M N G F consists of the epsilon solid solution and tin containing 0.2% copper in solution called zeta. The area L M F A represents the solid solution zeta.

The Liquidus Curve—The liquidus drops from the melting point of tin 232°C., to the eutectic point at 0.94% copper and at 227°C., and then rises rapidly upon further increase of copper content.

From 50-47% copper the primary constituent is the gamma solid solution. At D, 625°C., this phase reacts with liquid to form the solid solution eta. From D-C (alloys of 47-8% copper) the primary constituent is eta. At C this phase reacts with the liquid to form the epsilon solid solution which is the primary constituent separating from the liquid along the curve from C-B (8-0.94% copper). The solidus curve is formed by joining the points A F B G H J; the complicated form is due to peritectic reactions of the solid phases with this liquid.

The existence of the solid solution of 0.2% copper in tin, zeta, was found by the painstaking investigations of Haughton. According to Hanson, Sanford, and Stevens, there is no zeta solid solution.

There has been considerable dispute about the percentage of copper in the eutectic, although its location at 227°C. appears well established.

Description of Fields Shown on Diagram—The area D K E represents a mixture of the solid phase gamma, and liquid.

The field C H J K D represents a mixture of crystals of solid solution eta and liquid.

The area B G H C represents the solid phase epsilon and liquid.

The region F B A represents the solid solution zeta and liquid.

The area O P J H represents a heterogeneous mixture of the solid solutions eta and epsilon.

The area N O H G represents the solid solution zeta and liquid.

Transformations in the Solid State—In the diagrams of several investigators a hypothetical transformation of the epsilon constituent to epsilon prime, has been given at 186 and 189°C. This was based largely on determinations of thermal resistance but microscopic examinations show no difference between the two solid solution structures. These horizontals are not included in Fig. 1 because of insufficient evidence and also due to the X-ray investigations of Westgren and Phragmen, who find no evidence of such transformation. Horizontals at 160 and 18°C. are also removed from the present diagram because of insufficient evidence to support inclusion. According to some investigators they are alleged to be associated with the transformations of tin in the allotropic changes: Gamma to beta and beta to alpha respectively. It is felt that a small amount of copper in tin is effective in inhibiting such transformations.

From 40-41% copper the solidus rises rapidly from 227-415°C. In this narrow field the solidified metal consists of the homogeneous phase epsilon. Long annealing at suitably high temperatures are essential to attain the equilibrium single phase structure of this epsilon solid solution.

From 41-50% copper the solidus J H at 415°C. is also part of the peritectic horizontal; H is the peritectic point.

Constitution of Tin-Phosphorus Alloys

By W. A. Cowan* and G. O. Hiers†

The tin-phosphorus system has only been partially investigated. The alloys containing from 0-50% phosphorus were examined by thermal and microscopic methods by A. C. Vivian, who drafted a provisional diagram. The work was attended by great experimental difficulty, as it was found that for the formation of alloys above 2.5% phosphorus the vapor phase was necessary. For alloys containing more than 8.5% phosphorus, pressure above atmospheric was required. Since the pressure is usually considered invariant in metallurgical thermal concentration diagrams, the tin-phosphorus system is noteworthy and represents pioneer effort.

It has been suggested that the diagram as shown may be regarded as a sloping section cut through a three dimensional model having three variables: Concentration, temperature, and pressure. However, as the pressures used were not measured and necessarily varied in the different experiments, no definite section or plane can be considered. The investigator felt it advisable to reject the view of a three-dimensional model since the pressure functioned solely in determining the phosphorus concentration.

With this explanation and also the mode of experimentation, the diagram to be described must not in any way be regarded as final. Haughton's nomenclature has been adopted in discussing this work, as his diagram attempts a provisional representation of equilibrium conditions which is in keeping with phase rule requirements.

Alloys from the tin end of the diagram begin to solidify along the liquidus AB which mounts almost vertically up to 400°C. and then slopes to 550°C. for a phosphorus content of 8.5%, shown at the point B. From theoretical considerations Haughton shows the eutectic containing a minute quantity of phosphorus, but

as this quantity is unknown and so small, it is difficult to show on a diagram of the size plotted. Further work may establish the existence of the eutectic, but the cooling curves of Vivian certainly did not show it and for practical purposes its consideration can be rejected.

Alloys between B and C, from 8.5 to about 15.5% phosphorus, form two immiscible liquids at about 550°C. Dotted lines BB' and CC' illustrate in a limited way the concentrations and temperatures at which the conjugate solutions may exist. Somewhere just above 600°C. it is probable that the lines BB' and CC' join and the

Fig. 1—Tin-Phosphorus Constitution Diagram.

liquids of these compositions are mutually soluble, one liquid phase only being present. The line BC is the liquidus for alloys of the above concentrations. Therefore the area bounded by the liquidus curve ABC and the solidus AD, which is the horizontal at 232°C. and the almost vertical solidus DC, contains the alpha solid solution plus liquid. Below the solidus AD the alloy consists of pure tin and alpha solid solution.

The area EDCHG denotes the limits of the alpha solid solution, E indicates 14.7 and G 16.3% phosphorus. The nomenclature adopted in this area is Haughton's inter-

*Asst. Chief Chemist and †Metallurgist, National Lead Co., New York
This article not revised for this edition.

pretation of the experimental results obtained by Vivian and the line HG shows the maximum solubility of tin in the compound Sn_3P_4 . Vivian's notation in this area is confusing and does not fulfill phase rule conditions.

The area CHJ represents two phases, alpha solid solution and liquid metal. The liquidus line CJ meets the solidus CHJ at the first definite eutectic point J at 20% phosphorus. Alloys of increasing phosphorus content begin to freeze along an ascending liquidus JL to the maximum temperature at L, the point of total freezing for a single concentration of the beta solid solution. The point L may justifiably be regarded as the compound Sn_3P_4 from its mode of freezing, but more experimental data will prove or disprove such a hypothesis. The solidus of alloys of concentrations between C and L is shown by the line CH, eutectic horizontal HJK, and line KL. The area JKL represents the existence of two phases: Beta solid solution, which is a probable solid solution of tin in Sn_3P_4 , and liquid metal.

The beta solid solution is bounded on the one side by the solidus KL and the line of solid solubility KM, and on the other side by the solidus LO and line of solid solubility ON. Vivian's results show a possible junction of solid solubility lines KM and ON at about 440°C ., but for theoretical requirements it is necessary to show a solid solution as an area and not as a line of invariant concentration.

Alloys in the area GHJKM consist of the alpha solid solution plus beta solid solution.

The area LOP denotes mixtures of beta solid solution plus liquid. The liquidus LP intersects the solidus LOP at the second eutectic P.

Proceeding to higher compositions of phosphorus the liquidus rises to the point Q at 580°C . and then supposedly proceeds along the horizontal QRV.

Alloys of composition Q and of increasing phosphorus content are believed to form conjugate solutions above 580°C . The line of liquid miscibility QQ' is drawn dotted to indicate this probability.

At about 43% phosphorus and at 580°C ., a compound which would have a formula SnP , appears and the line RST denotes its concentration. Alloys in the area ONTSP consist of two phases: The beta solid solution plus the compound SnP .

Concentrations of phosphorus greater than 43% indicate the existence in the solid state of the compound SnP , and elemental red phosphorus, but such mixtures have received little study.

Constitution of the Tin-Antimony-Copper Alloys Used As Bearing Metals

By O. W. Ellis*

The tin-antimony-copper system has been the subject of considerable investigation^{1,2,3} but no work on the constitution of these alloys has yet been published. The following discussion, which is mainly concerned with the industrial alloys of this system, would therefore require some alteration to bring it into strict line with equilibrium requirements.

The constituents present in these high tin ternary alloys, *as cast*, are four in number, as follows:

1. The alpha solid solution, containing tin and copper. In these alloys, *as cast*, this constituent is characterized by a cored structure, which, however, can be removed by annealing the alloys for sufficient time at, for example, 100°C.

2. A constituent present in these alloys in the form of needle-shaped crystallites which vary in size according to the rate at which the alloy is cooled. It seems likely that in these alloys, *as cast*, the needle-shaped constituent, if not the intermetallic compound, CuSn, approaches it closely in composition. If these alloys are sufficiently annealed, equilibrium is reached as a result of the formation of the epsilon solid solution (see "Constitution of Tin-Copper Alloys," in this Handbook).

3. A constituent present in these alloys in the form of needle-shaped crystallites of a solid solution, eta, containing approximately 61.5% copper. These crystallites are not present in alloys containing less than 8% copper, and will not be referred to in the subsequent discussion of this system.

4. The intermetallic compound of tin and antimony, SnSb, containing approximately 50.4% antimony, which appears in the microstructure of these alloys, *as cast*, in the form of very sharply defined cubes and sections of cubes. Whether, under conditions of equilibrium, this compound would be replaced by the beta solid solution of the tin-antimony system is uncertain. The constitution of the latter system deserves much fuller investigation.

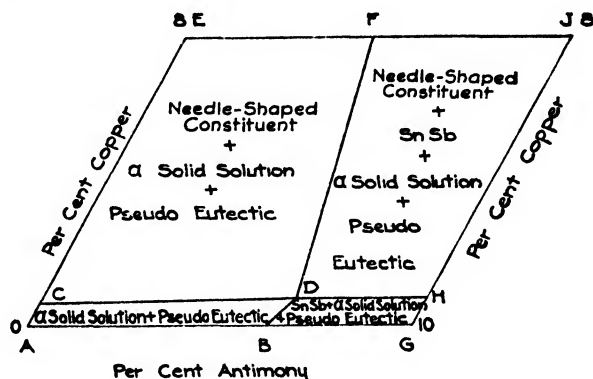

Fig. 1—Tin-Antimony-Copper Constitution Diagram.

Fig. 2—Contours of liquidus surface of space model for tin corner of system.

*Director of Metallurgical Research, Ontario Research Foundation, Toronto, Canada.

It is convenient to arrange the alloys in four groups in accordance with their microstructure, as shown in Fig. 1.

1. The first group of alloys, *as cast*, are characterized by a hypoeutectic structure, comprising alpha solid solution and a eutectic, or pseudo-eutectic.

2. The alloys in the second group, *as cast*, contain three micro-constituents: The needle-shaped constituent; the alpha solid solution; and the pseudo-eutectic already described.

3. The third group of alloys, *as cast*, comprise three micro-constituents: The intermetallic compound, SnSb; the alpha solid solution; and pseudo-eutectic. The proportion of pseudo-eutectic in these alloys is very small.

4. The fourth group of alloys, *as cast*, comprise four micro-constituents: The needle-shaped constituent; the intermetallic compound, SnSb; alpha solid solution; and pseudo-eutectic, of which the proportion is very small.

These four groups lie within the areas outlined in Fig. 1. Group 1 occupies the area ABDC; group 2, the area CDFE; group 3, the area BGHD; and group 4, the area DEJF.

The contours of the liquidus surface of the tin corner of the space model for this system* are shown in Fig. 2. The solidus for all the alloys covered by this diagram is 225°C. which is the eutectic temperature of the tin-copper system. In alloys which contain SnSb as a separate microconstituent, SnSb begins to crystallize on slow cooling at a temperature of 248°C. Rapid cooling has the effect of suppressing the crystallization of SnSb at 248°C. in antimony-rich alloys in the neighborhood of the boundaries BD and DF. It is possible that this effect might be of some importance in its bearing upon the antifrictional behaviour of the alloys lying near the boundaries BD and DF, and it may be well to emphasize the fact that the further removed an alloy is from these boundaries, the less likely is the normal crystallization of SnSb to be prevented.

Structure of Tin-Antimony-Copper Alloys Used As Bearing Metals

By O. W. Ellis*

By referring to the data sheet dealing with the constitution of the tin-antimony-copper alloys it will be seen that the alloys of this system, which are of industrial importance, may be divided into 4 groups as follows:

1. The first group of alloys, *as cast*, are characterized by a structure, comprising alpha solid solution and a eutectic, or pseudo-eutectic.

2. The alloys in the second group, *as cast*, contain 3 microconstituents: The needle shaped constituent, the alpha solid solution, and the pseudo-eutectic.

3. The third group of alloys, *as cast*, comprise 3 microconstituents: The inter-metallic compound, SnSb; the alpha solid solution; and pseudo-eutectic. The proportion of pseudo-eutectic in these alloys is very small.

4. The fourth group of alloys, *as cast*, comprise 4 microconstituents. The needle shaped constituent, intermetallic compound, SnSb; alpha solid solution; and pseudo-eutectic, of which the proportion is very small.

These 4 groups lie within the area outlined in Fig. 1. Group 1 occupies the area ABDC; group 2, the area CDFE; group 3, the area BGHD; and group 4 the area DHJF.

The microstructure of typical members of each of these groups is shown in Figs. 2 to 7. In all cases the alloys were poured at a temperature of 400°C. into a vertical mold approximately 1¼ in. in dia. and 7½ in. deep. which was heated to a temperature of 100°C. prior to casting. The samples for micro-examination were cut from the castings at a point about ½ in. from the bottom. The section photographed was near the center of the casting.

Fig. 2 is the structure of an alloy containing approximately 95.5% tin, 4% antimony, and 0.5% copper. It may be taken as representative of the structure of the alloys of group 1, which lie within the area ABDC of Fig. 1. The lighter areas are sections of primary alpha solid solution of the ternary system; the darker areas are sections of pseudo-eutectic. The small white crystallites noticeable within the darker areas are of the needle shaped constituent, which is itself a constituent of the pseudo-eutectic.

Fig. 3 is the structure of an alloy containing approximately 94% tin, 2% antimony, and 4% copper. This may be considered as a representative structure of the alloys of group 2, which lie within the area CDFE of Fig. 1 (see also Fig. 4). In this photomicrograph the needle shaped constituent is clearly visible. It was the first constituent of this alloy to freeze on cooling. The gray areas are sections of the alpha solid solution of the ternary system; the black areas, containing here and there minute crystallites of the needle shaped constituent, are sections of pseudo-eutectic.

Fig. 4 is the structure of an alloy containing approximately 86% tin, 6% antimony, and 8% copper. The structure of this alloy is similar to that shown in Fig. 3. The proportion of pseudo-eutectic in this alloy is, however, so small as to make it difficult to see it at the magnification used in this photomicrograph. The proportion of pseudo-eutectic in these alloys decreases as their antimony and copper contents increase.

Fig. 5 is the structure of an alloy containing approximately 91.5% tin, 8% anti-

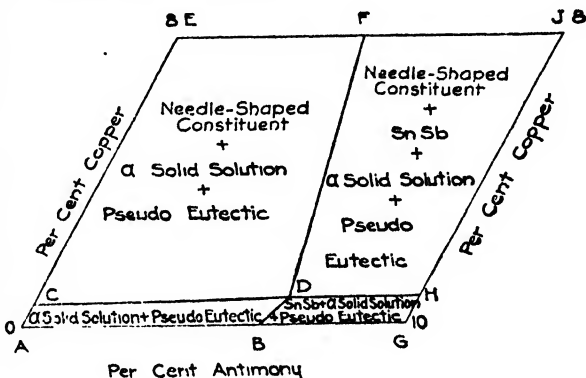

Fig. 1.—Tin-Antimony-Copper Constitution Diagram.

mony, and 0.5% copper. This may be considered as a representative structure of the alloys of group 3, which lie within the area BGHD of Fig. 1. The outstanding

Fig. 2—Structure of an alloy containing approximately 95.5% tin, 4% antimony, and 0.5% copper. $\times 150$.
 Fig. 3—Structure of an alloy containing approximately 94% tin, 2% antimony, and 4% copper. $\times 150$.
 Fig. 4—Structure of an alloy containing approximately 86% tin, 6% antimony, and 8% copper. $\times 150$.
 Fig. 5—Structure of an alloy containing approximately 91.5% tin, 8% antimony, and 0.5% copper. $\times 150$.
 Fig. 6—Structure of an alloy containing approximately 89.5% tin, 10% antimony, and 0.5% copper. $\times 150$.

feature of this structure is the constituent SnSb, which is present in the alloy in the form of cubes, sections of which are clearly seen in the photomicrograph. This constituent was the first to separate from the melt on cooling. It is imbedded in a matrix consisting almost entirely of alpha solid solution. The proportion of pseudo-eutectic present in the alloy is so small that it is impossible to detect at the magnification used.

Fig. 6 is the structure of an alloy containing approximately 89.5% tin, 10% antimony, and 0.5% copper. This photomicrograph is a companion to Fig. 5 and is introduced for the purpose of emphasizing the apparent effect of the needle shaped constituent on the size of the cubes of the tin-antimony compound, SnSb.

Fig. 7 is the structure of an alloy containing approximately 82% tin, 10% antimony, and 8% copper. This may be considered as a representative structure of the alloys of group 4, which lie within the area DHJF of Fig. 1. Here sections of the needle shaped constituent, which was the first to freeze on cooling, and of cubes of the intermetallic compound, SnSb, which was the second constituent to freeze on cooling, are

found in a matrix of alpha solid solution. Some pseudo-eutectic is present in the structure but in such small amounts that it is difficult to detect at a magnification of 150 diameters.

It will be noted that the size of the cubes in Fig. 7 is considerably greater than that of the cubes in Fig. 6. This greater cube size is characteristic of the alloys of high copper content, other things apparently being equal. Ellis and Karelitz¹

¹O. W. Ellis and G. B. Karelitz, Study of Tin-Base Bearing Metals, Trans., Am. Soc. Mech. Engrs., 1928, MSP-50-11, p. 13.

are of the opinion that "the difference in crystal size may be accounted for by assuming that the presence of primary CuSn^3 facilitates the precipitation of SnSb and, as a result, a few large cubes are formed where, in the absence of the inoculating medium CuSn , a greater number of small cubes would be precipitated. The presence of needles of CuSn within the cubes of SnSb is a common occurrence in the alloys of high copper content."

Rapid cooling has the effect of suppressing the crystallization of SnSb in antimony-rich alloys in the neighborhood of the boundaries BD and DF of Fig. 1. It is therefore possible to obtain structures free from cubes of SnSb in certain alloys, if the same be cooled from the liquid state at a sufficient rate. This effect, in an alloy containing approximately 90% tin, 8% antimony, and 2% copper, is brought out in Fig. 8 and 9, the former representing the average structure toward the center of an ingot of this alloy, the latter the average structure near the edge. It is possible that this effect might be of some importance in its bearing upon the antifrictional behavior of the alloys lying near the boundaries BD and DF, and it may be well to emphasize the fact that the further removed an alloy is from these boundaries, the less likely is the normal crystallization of SnSb to be prevented.

In the case of alloys further removed from these boundaries the rate of cooling

Fig. 7—Structure of an alloy containing approximately 82% tin, 10% antimony, and 8% copper. $\times 150$. This represents the average structure at the center of the ingot.
 Fig. 8—Structure of an alloy containing approximately 90% tin, 8% antimony, and 2% copper. $\times 150$. This represents the average structure toward the center of the ingot.
 Fig. 9—Same alloy as Fig. 8. This represents the average structure at the edge of the ingot. $\times 150$.

³See the remarks on the needle-shaped constituent in the article on the constitution of these alloys.

has an important effect on the dimensions of the cubes of SnSb, these decreasing in size as the rate of cooling is increased. The pouring temperature, except in so far as it affects the rate of cooling, is insignificant in its action in this regard.

In certain cases, however, the pouring temperature has quite an important effect upon the manner in which the needle-shaped constituent distributes itself. Hudson and Darley³ have shown in the case of an alloy containing 89.0% tin, 8.7% antimony, and 2.3% copper, poured at known temperatures into an iron ingot mold $1\frac{1}{2}$ in. long by $\frac{1}{2}$ in. wide by $\frac{1}{2}$ in. deep, previously heated to varying degrees, that (a) in those cases where the pouring temperature was above about 300°C., the primary needles separate from solution in the form of long,

Fig. 12—Macrostructure of 3 $\frac{1}{4}$ % antimony-3 $\frac{1}{4}$ % copper alloy, as cast. Fig. 13—Same as Fig. 12, but annealed.

Fig. 14 and 15 same as Fig. 12 and 13 at 250X.
Fig. 16 and 17 same as Fig. 12 and 13 at 250X.

feathery or chain-like crystallites, generally arranged in a very distinct angular fashion and frequently in clearly defined triangular groups (Fig. 10); and (b) in those cases where the pouring temperature was about 300°C. or below, the needle-shaped constituent occurs chiefly as shorter and often much thicker needle shaped crystals or in star-shaped forms. Well marked triangular groups were rarely seen and the general "grain size" was much smaller (Fig. 11).

Hudson and Darley suggest that for each alloy of this system there will exist a critical temperature below which pouring should always be conducted if the triangular groupings of the crystallites of the needle shaped constituent are to be avoided, it being assumed that triangular groupings are objectionable on account of their effect on the properties of the alloy. To what extent, however, the results of experiments on relatively heavy sections can be applied to the thin linings ($\frac{1}{8}$ - $\frac{1}{4}$ in.) of white metal so widely used in engineering work is open to question. In general, pouring temperatures of from 400-450°C. do not appear to have a deleterious effect on the alloys of this system when cast in the form of thin linings.

Since bearing metals are used upon their structures has been deemed worthy of consideration. In this connection Homer and Plummer⁴ have studied two representative tin-antimony-copper alloys,

³O. F. Hudson and J. H. Darley, *Constitution and Structure of Certain Tin-Antimony-Copper Alloys*, *J. Inst. Metals*, 1920, v. 24, p. 361.

⁴O. E. Homer and H. Plummer, *Tech. Pub. of International Tin Research and Dev. Council*, Ser. A, No. 5, Aug., 1937.

samples of which were cut from cast rods $\frac{1}{2}$ in. in dia. The structures of these alloys (after polishing and etching) were photographed both before and after annealing at 165° C. for 1 week in a thermostatically controlled oven.

Fig. 12 and 13 show the macrostructure typical of the 3½% antimony-3½% copper alloy as cast and as annealed, respectively. These photographs support the view that any change in mechanical properties undergone by these alloys as a result of annealing is not due to a change in grain size.

Typical microstructures of this same alloy, as cast and as annealed, are shown in Fig. 14 and 15 at a magnification of 250 dia. The principal effects of annealing have been the coalescence of the particles of needle-shaped constituents and the effacement from the solid solution of the vague dark patches which are evidence of its inhomogeneity in the "as cast" state.

Photomicrographs, at a magnification of 500 dia., of typical sections of the 10% antimony-3½% copper alloy, as cast and as annealed, are shown in Fig. 16 and 17. Annealing this alloy causes the cubes of SnSb to spheroidize and numerous small particles of what appears to be SnSb to precipitate from the solid solution.

The effects of annealing upon the mechanical properties of these alloys are dealt with in the article on "Properties of Tin-Base Bearing Alloys."

Physical Constants of Tin

By Dr. C. L. Mantell*

Introduction—Tin metal having a purity as high as 99.9+% has long been available in the form of "Straits Tin," particularly those under the designations of Banka, Billiton, and Penang. Most of the properties of the metal have been determined on these grades of metal, a typical analysis of which is: Tin 99.950%, antimony 0.007, arsenic nil, lead trace, bismuth nil, copper 0.018, iron 0.045, silver nil, sulphur trace. Some of the recent work has been done on 99.99+ metal, particularly Chempur tin, a typical analysis of which is: Tin 99.9918%, antimony 0.0031, arsenic nil, lead 0.0025, bismuth 0.0004, copper 0.0004, iron 0.0016, silver nil, sulphur 0.0002, cobalt nil.

Small amounts of copper appreciably harden tin, while even traces of iron affect the color. With increasing purity the metal becomes appreciably more corrosion resistant to a number of electrolytes.

Allotropy of Tin—

Tin exists in a number of allotropic forms, shown diagrammatically in Fig. 1. At low temperatures the stable form is gray cubic or alpha tin, which changes at 18°C. to ordinary white tetragonal or beta tin. This suffers transposition at 161°C. to the so-called rhombic brittle or gamma tin, which at 232°C. passes into the molten state. Simson¹ states that according to his X-ray studies, gamma tin is hexagonal.

Ordinary tin changes into a gray powder when exposed to extremes of cold. Medallions, coins, and antiques in museums acquire a surface crust of powdery gray tin which gradually grows, seemingly self catalyzed, until disintegration results. This is the so-called "tin pest" or "disease" of the museums.

Fig. 1—Constitution of the allotropic forms of tin.

Atomic Weight—The element tin has the atomic No. 50. Its atomic weight is 118.70 according to the most recently determined and accepted values. According to Aston¹ there are 11 isotopes, which, arranged in order of relative abundance, have the following values: 120, 118, 116, 119, 117, 124, 122, 121, 112, 114, 115. Other atomic properties are given in Table I.

Crystal Form—Bijl and Kolkmeijer² show from their X-ray studies of gray tin that it crystallizes in the cubic system. Its space lattice is body-centered tetragonal with an edge of unit cube $a = 6.46$ Å units.

According to Polanyi and Schmid white tin crystallizes in a modified tetragonal lattice, containing in the unit cell four atoms of coordinates 000, $0\frac{1}{2}$, $\frac{1}{2}0$, and $\frac{1}{2}\frac{1}{2}$.

Color—The color of tin is white, with a slightly bluish tinge. Compared with tin, nickel is brown and chromium is definitely blue. Tin is whiter than silver or zinc. Exceedingly thin films of tin transmit various shades of brown when light is caused to pass through the film. The metal has a brilliant luster and when highly polished has high light reflectivity. The luster depends to a great extent upon the temperature at which the metal is poured when cast. If the temperature should be too high, iridescent colors may show on the surface as the result of oxide films. If the pouring temperature should be too low, the surface is dull. Small amounts of foreign metals such as lead, arsenic, antimony, and iron decrease the luster of tin and impart a yellowish tinge to the metal.

Density—Tin (purity 99.992%) has a density of 7.2984 g. per cc. at 15°C. in the cast condition. Values for the density (in g. per cc., or sp.gr.) for the different allotropic forms as well as in the molten condition are given in Table II.

Table II
Density Values

Compressibility—The compressibility or percentage change in volume with unit change in pressure of 1 megabar (0.987 atmospheres; 14,504 psi.) of refined tin (99.99+) is given by Adams, Williamson and Johnston¹⁰ as 1.89×10^{-6} at 20°C. at atmospheric pressure, and 1.64×10^{-6} at 10,000 megabars pressure. Richards¹¹ gives a figure of 1.9×10^{-6} per megabar at 300 megabars pressure.

Thermal Expansivity—Data for the thermal expansion of tin is given in Table III for linear and cubic expansion coefficients.

Table III
Thermal Expansion

Linear expansion—

	6.67 kilojoules per g atom	Glaser ²⁴

Boiling Point—Greenwood²⁵ and Mott²⁶ give the boiling point of tin as 2270°C., but the International Critical Tables place the value at 2260°C. The metal is non-volatile at ordinary melting, casting, and alloying temperatures. At temperatures around 1000°C. the vapor pressure is only 10⁻⁸ mm. mercury. According to the International Critical Tables, the latent heat of vaporization is 325 kilojoules per g. atom at the boiling point 2260°C. This is approximately 88,600 calories per mol (118.70 g.). The vapor pressure and related data are given in Table VI.

Table VI
Boiling Point and Vapor Pressure

Boiling point	2270°C.	Greenwood ²⁵ and Mott ²⁶

15°C.	0.1828 absolute units	Kirchhoff and Hansemann ³¹
0°C.	0.1628 absolute units	Lorenz ³²
100°C.	0.1423 absolute units	Lorenz ³²
200°C.	0.145 absolute units	Jakob ³³
283°C.	0.081 absolute units	Könne ³⁴
417°C.	0.079 absolute units	Könne ³⁴
498°C.	0.078 absolute units	Könne ³⁴

Thermal Conductivity—The thermal conductivity of tin is low as compared to silver. Table VII gives absolute units (cal. per sec. per sq.cm. per cm. thickness per °C.) at various temperatures. A value of 0.15 absolute units is equivalent to 432 B.t.u. per hr. per sq.ft. per in. thickness per °F.

Fluidity—Fluidity is the reciprocal of viscosity which Sauerwald and Töpler⁴ studied for tin and obtained the figures in Table VIII.

Table VIII
Fluidity Data

Electrolytic Solution Potential—According to the usual terminology, tin is electronegative to elements it replaces in solution and electropositive to those which displace it from solution. In simple solutions of sulphates, tin is electronegative to the precious elements, copper, hydrogen, and electropositive to elements like iron, aluminum, magnesium, zinc, and cadmium. In other than simple solutions, the position of tin may change, and it may be found to be electropositive to metals to which in sulphate solutions it acted in an electronegative manner. As to the corrosion of tin in coatings, no valid reasoning can be based on the electrochemical position of the metal in simple sulphate solutions. Reference should be made to extensive papers on this subject.⁴

Mechanical Properties—The tensile strength of tin is low and the pressure for critical plasticity is slightly above this value. Tin is readily extruded, drawn, stamped, and spun. It does not work harden appreciably. The elastic limit is low. Its hardness is low, decreasing with increase of temperature. High purity tin is extremely ductile and plastic. Small amounts of impurities, particularly lead, antimony, copper, iron, bismuth, and silver, harden the metal, increase its tensile strength and reduce ductility. Table XII contains values for a number of important properties.

Other Properties—Many major uses of tin as a coating or alloying metal depend on the wetting power, surface tension, contraction and expansion on freezing, diffusion and other physical properties which are listed in Table XIII.

Properties of Tin-Base Bearing Alloys

By O. W. Ellis*

Introduction—The tin-base bearing metals, known commercially as "babbitt metals" or "babbitts", are essentially alloys of tin, antimony, and copper, to which as much as 30% of lead may be added—largely for the purpose of reducing their cost. Of the elements which materially improve these alloys cadmium is perhaps the most important; nickel is stated to be of value, but little definite information regarding its effects has so far been published.¹ Of elements to be avoided entirely, zinc and aluminum are the most important. Arsenic, bismuth, and iron should be limited in amount. The specifications of the A.S.T.M. (endorsed by the A.F.A.) and of the S.A.E. for white bearing metal alloys may be referred to in this connection.

In the former (A.S.T.M. Designation: B 23-26), paragraphs 4 and 5 read as follows:

4. The alloys shall conform to the following requirements as to chemical composition, within the limits specified in Section 5:

Alloy Grade* 'ON	Tin, %	Antimony, %	Lead, %	Copper, %	Iron, max., %	Arsenic, max., %	Zinc, %	Aluminum, %
1	91	4½	0.35 max.	4½	0.08	0.10	none	none
2	89	7½	0.35 max.	3½	0.08	0.10	none	none
3	83½	8½	0.35 max.	8½	0.08	0.10	none	none
4	75	12	10	3	0.08	0.15	none	none
5	65	15	18	2	0.08	0.15	none	none

*Grades Nos. 6-12, which represent lead-base bearing metals, have been omitted from this table to save space.

5. The following permissible variations in the percentages of the desired elements specified in Section 4 will be allowed, but shall not apply to the maximum percentages of impurities specified:

Percentage of Element Specified	Permissible Variations Over or Under the Specified Value. Units of Per Cent
Not over 2%.....	0.25
Over 2-5%, incl.....	0.50
Over 5-10%, incl.....	0.75
Over 10%	1.00

In the latter, the limits for the chemical compositions specified for metal in ingot form are closer than the limits specified for cast products, as allowances have been made for variations in the chemical content due to casting. The three S.A.E. specifications are as follows:

Specification No. 10, Babbitt

	Cast Products	Ingot
Tin, % min.....	90	90.75
Copper, %.....	4-5	4.25-4.75
Antimony, %.....	4-5	4.25-4.75
Lead, % max.....	0.35	0.35
Iron, % max.....	0.08	0.08
Arsenic, % max.....	0.10	0.10
Bismuth, % max.....	0.08	0.08
Zinc and aluminum.....	none	none

When finished bronze-backed bearings are purchased, a maximum of 0.6% lead is permissible in scraped samples provided a lead-tin solder has been used in bonding the bronze and the babbitt.

General Information—This babbitt is fluid and may be used for bronze-backed bearings, particularly for thin linings such as are used in aircraft engines. It is also suitable for die castings.

*Director of Metallurgical Research, Ontario Research Foundation, Toronto, Canada.

Specification No. 11, Babbitt

	Cast Products	Ingot
Tin, % min.....	86.00	87.25
Copper, %.....	5.00-6.50	5.50-6.00
Antimony, %.....	6.00-7.50	6.50-7.00
Lead, % max.....	0.35	0.35
Iron, % max.....	0.08	0.08
Arsenic, % max.....	0.10	0.10
Bismuth, % max.....	0.08	0.08
Zinc and aluminum...	none	none

When finished bronze-backed bearings are purchased a maximum of 0.6% lead is permissible in scraped samples provided a lead-tin solder has been used in bonding the bronze and the babbitt.

General Information—This is a rather hard babbitt which may be used for lining connecting rod and shaft bearings which are subjected to heavy pressures; its "wiping" tendency is slight. It is also suitable for die castings.

Specification No. 12, Babbitt

	Cast Products	Ingot
Antimony, %.....	9.50-11.50	10.25-10.75
Copper, %.....	2.25- 3.75	2.75- 3.25
Lead, % max.....	26.00	25.25
Tin, % min.....	59.50	60.00
Iron, % max.....	0.08	0.08
Bismuth, % max.....	0.08	0.08
Zinc and aluminum.....	none	none

General Information—This is a relatively cheap babbitt and is intended for bearings subjected to moderate pressures. It is also suitable for die castings.

Effects of Various Elements on Microstructure of Bearing Alloys—The presence of zinc and arsenic in bearing metals is looked upon with disfavor. According to Freeman and Brandt³ and Roast and Pascoe,⁴ arsenic increases the resistance of these alloys to deformation at all temperatures, while zinc has a similar effect at 100°F. but causes little or no change in their properties at room temperature.⁵ Zinc has been found to have a marked effect upon the microstructure of certain of these alloys,⁶ the cubes of SnSb tending to coalesce and form star-shaped groups. At the same time, though normally of a reddish hue, the alloys become white when as little as 0.032% of zinc is added.

Small quantities of aluminum (1%) modify the microstructure of these alloys, causing the cubes to disappear. Alloys containing aluminum have a fine, globular structure when rapidly solidified; but liquation occurs on slow freezing, the aluminum (in combination with a little copper and some antimony) tending to rise to the tops of castings during freezing.⁷

Bismuth is objectionable because it forms with tin a eutectic which melts at 137°C., so that at temperatures in excess of this its fusibility appreciably lowers the strength of alloys containing it.

In high tin alloys (such as A.S.T.M. Grades No. 1-3 and S.A.E. Specifications No. 10 and 11) lead is limited to 0.35%. This is because of the deleterious effect of lead upon the strength of these alloys at high temperatures (150°C. or more). Lead forms with tin a eutectic which melts at 183°C. Bearings which exceed this temperature naturally become fragile because of the formation within them of a liquid phase.

Cadmium is without appreciable effect on the structures of these alloys if lead be absent. In alloys free from lead a constituent, probably a eutectic, appears when the cadmium content reaches about 3% in a bearing metal containing 7% antimony and 3.5% copper. Increase in the antimony content appears to admit of more cadmium being retained in solid solution; on this account the fusible constituent, which melts at about 170°C., is prevented from appearing. Conversely, a reduction in antimony causes the eutectic to appear at a lower cadmium content.⁸ When lead is present, it forms with cadmium and tin a ternary eutectic which melts at 145°C. Bearings, therefore, cannot be operated at temperatures in excess of this point without danger of "wiping" and serious loss of strength.

Mechanical Properties at Room Temperature—Grades No. 1-5 of the above A.S.T.M. Designation: B 23-26 have been intensively investigated by Freeman and Woodward.¹ The main results of their work are given in Table I.

Table I
Composition and Physical Properties¹ of White Metal Bearing Alloys

Alloy No.	—Specified Composition— of Alloys, %				Sp.gr.	—Compositions of Alloys— Tested, %				—Yield— Point, psi. ²	
	Cu	Sn	Sb	Pb		Cu	Sn	Sb	Pb	20°C.	100°C.
1	4.5	91.0	4.5	7.34	4.56	90.9	4.52	none	4,400	2,650
2	3.5	89.0	7.5	7.32	3.1	89.2	7.4	0.03	6,100	3,000
3	8½	83½	8½	7.46	8.3	83.4	8.2	0.03	6,600	3,150
4	3.0	75.0	12.0	10.0	7.52	3.0	75.0	11.6	10.2	5,550	2,150
5	2.0	65.0	15.0	18.0	7.75	2.0	65.5	14.1	18.2	5,050	2,150

Alloy No.	Johnson's Apparent Elastic Limit, psi. ³		Ultimate Strength, psi. ⁴		Brinell Hardness ⁵		Melting Point		Temp. of Complete Liquefaction		Proper Pouring Temp.	
	20°C.	100°C.	20°C.	100°C.	20°C.	100°C.	°F.	°C.	°F.	°C.	°F.	°C.
1	2,450	1,050	12,850	6,950	170	80	433	223	825	441
2	3,350	1,100	14,900	8,700	24.5	12.0	466	241	669	354	795	424
3	5,350	1,300	17,600	9,900	27.0	14.5	464	240	792	422	915	491
4	3,200	1,550	16,150	6,900	24.5	12.0	363	184	583	306	710	377
5	3,750	1,500	15,050	6,750	22.5	10.0	358	181	565	296	690	366

¹The compression test specimens were cylinders 1½ in. in length and ½ in. dia., machined from chill castings 2 in. in length and ¾ in. in dia. The Brinell tests were made on the bottom face of parallel machined specimens cast in a 2 in. dia. by ¾ in. deep steel mold at room temperature.

²The values for yield point were taken from stress-strain curves at a deformation of 0.125% reduction of gage length.

³Johnson's apparent elastic limit is taken as the unit stress at the point where the slope of the tangent to the curve is 1½ times its slope at the origin.

⁴The ultimate strength values were taken as the unit load necessary to produce a deformation of 25% of the length of the specimen.

⁵These values are the average Brinell number of three impressions on each alloy, using a 10 mm. ball and a 500 kg. load applied for 30 sec.

Table II
Brinell Hardness Numbers, Ultimate Strength, Limits of Proportionality, and Yield Points of Tin-Base Bearing Metals

Antimony, %		Copper, %				
		0.5	1	2	4	8
2	Hardness	9.5	11.3	12.3	13.0	15.3

	Yield point, psi.	8,240	9,440	9,780	11,920	14,580

Values for Brinell hardness numbers, limits of proportionality, and yield points in compression, and compressive strengths (loads per unit initial area required to compress test pieces 0.250 in. per in. length) of representative alloys of the tin-antimony-copper system are given in Table II taken from Ellis and Kareltz,⁸ to whose paper reference should be made for details.

A most important point brought out by Freeman and his collaborators was that the total deformation of the sample in the compression testing of babbitts is a function of the time of application of the load—a point sometimes overlooked by those reporting and studying results of tests on materials as plastic as are these alloys. What is true of the compression test is true also of other types of static tests.⁹ However, the known limitations of static tests do not discount their value. A Brinell test, for example, wherein the load is applied for a standard time (say, 30 sec.) is of considerable value for purposes of manufacturing control.

The properties in tension at room temperature of a number of tin-base bearing metals have been investigated by Munday, Bissett, and Cartland,¹⁰ Boegehold and Johnson,¹¹ Arrowsmith,¹² von Göler and Sachs,¹³ and others. The curves (Fig. 1a and 1b) are from Arrowsmith, whose tests were conducted on unmachined gravity die cast samples 0.226 in. in dia. with a gage length of 0.884 in. The samples were broken approximately 1 hr. after being cast. The rate of straining in these tests was about 0.017 in. per min.

Fig. 1a—Effect of cadmium on the properties of tin-base bearing metals.
(See Table IIA for meaning of symbols on curves).

The relationship between the properties of the tin-base bearing metals in compression and their Brinell hardness numbers is close enough to permit a fair estimate to be made of their properties in compression. Further, a relationship seems to exist between the endurance limits, tensile strengths, and Brinell hardness numbers of these alloys. Macnaughtan¹⁴ believes "that for exploratory purposes the Brinell hardness and tensile tests may prove to be a useful guide to the fatigue-resisting properties" of such materials.

Repeated blow drop tests¹⁵ and single blow drop tests¹⁶ on bearing metals have been the subject of considerable investigation. In the writer's opinion such tests, while of interest, serve no better than do Brinell hardness and tensile tests to assess the relative usefulness of these alloys in service. Reference should be

made to the original papers for information regarding the malleability of individual mixtures.

The endurance limit (20,000,000 cycles) of a $3\frac{1}{2}\pm\%$ copper-tin-base bearing metal (0.25% lead, 0.03% arsenic, trace of iron) poured at 350°C. into a mold at 150°C. increases from about 3,400 psi. with 3% antimony to about 4,400 psi. with 6% antimony, and to about 4,800 psi. with 9% antimony. Concurrently, the tensile strength (straining rate, 1.2 in. per sec.) increases from about 7,800 psi. to about 11,200 psi. and about 13,500 psi., respectively, while the Brinell hardness number (125 kg. load; 10 mm. ball; 30 sec.) rises from 15 to about 21 and about 26, respectively.¹⁴

Fig. 1b—Effect of cadmium on the properties of tin-base bearing metals
(See Table IIA for meaning of symbols on curves).

The impact resistance of tin-base bearing metals closely resembling A.S.T.M. Grades No. 1 and 3 has been measured by Herschman and Basil¹⁷ with the following results:

Alloy Grade No.	Izod Impact Numbers (ft.-lb.)				
	20°C.	60°C.	100°C.	150°C.	200°C.
1	$2\frac{1}{2}$	N. O.	3	$3\frac{1}{2}$	$2\frac{1}{2}$
3	$\frac{3}{4}$	1	1	$1\frac{1}{2}$	$1\frac{1}{2}$

The results of experiments by Karelitz and Ellis¹⁸ on the rolling of tin-base babbitts show the extent to which these alloys can resist plastic deformation without rupture. Carefully machined samples, $1\frac{1}{2}$ in. long, 1 in. wide, and $\frac{1}{8}$ in. thick, were given 13 passes through highly polished, 6 in. dia. rolls, the reduction in thickness per pass being 0.025 in. The final thickness of the samples was therefore 0.175 in.

No attempt was made to trim the samples when signs of cracking were observed. The results of the experiments are shown in the following table:

Sample No.	Cu (%)	Sb (%)	Condition After Rolling	Sample No.	Cu (%)	Sb (%)	Condition After Rolling
1	0.5	2	No cracks	14	2	8	Few large cracks
2	0.5	4	No cracks	15	2	10	Large deep cracks
3	0.5	6	No cracks	16	4	2	No cracks
4	0.5	8	Small cracks	17	4	4	No cracks
5	0.5	10	Few large cracks	18	4	6	Small cracks
6	1	2	No cracks	19	4	8	Large cracks
7	1	4	No cracks	20	4	10	Large cracks
8	1	6	No cracks	21	8	2	Very few cracks
9	1	8	Few large cracks	22	8	4	Very few cracks
10	1	10	Few large cracks	23	8	6	Few large cracks
11	2	2	No cracks	24	8	8	Large deep cracks
12	2	4	No cracks	25	8	10	Broken
13	2	6	No cracks				

Sample 25 showed definite signs of cracking after the second pass, samples 10, 14, 15, 19, and 20 after the fourth pass. Sample 25 failed completely during the twelfth pass.

Herschman and Basil¹¹ also conducted wear tests on these alloys, using a modified Amsler test in which a steel wheel (Brinell hardness number, about 240) rolled in circumferential contact with a bronze wheel fitted with a babbitt tire. A load of 5 lb. was placed on the steel wheel during test. A stream of kerosene was directed onto the babbitt near its area of contact with the steel. The losses of weight per 1,000 revolutions of Grades No. 1 and 3 were about the same and were definitely lower than those of Grades No. 6, 7, 8, 10, and 11, an alkaline earth metal "hardened lead," an 82/18 cadmium-zinc alloy, and a modified Grade No. 8 alloy containing 1.0% copper, 0.6% arsenic, 0.2% cadmium, and 0.2% nickel in place of part of the tin. The last alloy was the best of the latter group (that is, No. 6, 7, 8, 10 and 11 and the others noted); it had lost 0.6 g. after 50,000 revolutions as compared with 0.2 g. for Grades No. 1 and 3. Service tests on crankshaft bearings made of Grade No. 1 alloy, "hardened lead," Grade No. 10 alloy, and a 90/10 tin-copper alloy frequently used in U. S. Army truck motors showed that "the tin-base alloys were superior in their resistance to both the 'hardened lead,' and lead-antimony-tin alloy containing about 3% tin."

The results may here be noted of tests made by Jakeman and Barr¹² on behalf of the Tin Research Subcommittee of the British Nonferrous Metals Research Association with the primary object of ascertaining the comparative chemical action of lubricants upon tin-base and lead-base bearing metals. They found that under their conditions of test (using a journal friction testing machine with bearings fully lubricated by continuous circulation of oil) there was no marked chemical reaction between lubricants and alloys except where oils containing free fatty acid were used with alloys containing high percentages of lead. The tests also showed that, generally speaking, bearings made of high lead alloys showed greater frictional losses and wear than those made of high tin alloys.

Effects of Cadmium on Mechanical Properties of Tin-Base Bearing Metals—In Fig. 1a and 1b reference is made to alloys containing 1% of cadmium. These alloys merit attention. By interpolation of curves published by Macnaughtan¹³ the information given in Table III has been obtained.

Table IIA

Table III
Effects of Cadmium (1%) on Hardness and Strength of Tin-Base Bearing Metals
(Copper, 3½%; Lead, 0.04%)

Antimony, %	Cadmium, %	Tensile Strength, psi.	Brinell Hardness No.
4	{ Nil	9,200	17½
	{ 1	10,000	25
6	{ Nil	11,000	21
	{ 1	13,800	26
8	{ Nil	13,400	24
	{ 1	14,700	30½
10	{ Nil	13,800	26
	{ 1	15,900	32
12	{ Nil	14,400	27
	{ 1	16,900	33

The results of work by Haigh on an alloy containing 3½ copper and 7% antimony indicate that 1% cadmium increases its endurance limit at room temperature from about 4,600 psi. to about 5,500 psi. on the basis of 20,000,000 reversals of stress. Von Göler and Sachs" state that the hot strength of these alloys is "markedly increased at temperature up to 180° . . . The running properties are favorably influenced by the addition of cadmium. From the aspect of foundry technique these alloys . . . do not exhibit any peculiarities as compared with the usual high tin white metals."

Behavior of Alloys at High Temperatures—The behavior of tin-base bearing metals at high temperatures is considerably affected by small changes in composition. Bismuth and lead are objectionable on account of the fusibility of the eutectics which these metals form with tin. Opinions differ, though unimportantly, as to the effect of lead upon the mechanical properties of these alloys at high temperatures. Without doubt lead somewhat increases the strength and hardness of tin-base bearing metals at room temperature.* This effect, however, is almost entirely lost in A.S.T.M. Grades No. 1, 2 and 3 at temperatures between 90°C. and 125°C. Boegehold and Johnson" quote the following values for the compressive flow points, the tensile strengths, and the percentage elongations at 204°C. of a series of tin-base bearing metals containing about 7½% antimony and 7½% copper.

	Sn %	Sb %	Cu %	Pb %	Bi %	Compressive Flow Point, psi.	Tensile Strength, psi.	Elongation in 2 in., %
No. 1.....	82.87	7.51	7.55	1.97	...	260
No. 2.....	84.26	7.80	7.94	trace	...	500
No. 3.....	82.50	7.50	7.50	2.00	0.5	190
No. 4.....	85.0	7.50	7.50	0	...	1570-1630	116.0
No. 5.....	83.0	7.50	7.50	2.0	...	470- 510	1.0

These results indicate that little is to be gained by introducing lead into high tin alloys for the mere purpose of increasing their resistance to deformation, save where the temperatures of the bearings will not exceed about 90°C.

The importance of cadmium as a strengthener of tin-base bearing metals cannot be lightly dismissed. The behavior of a number of such alloys at elevated temperatures has been the subject of work by Greenwood" and by Homer and Plummer.

Of these workers, the first investigated the tensile properties of cast strips of white metal, 6 in. long, ¼ in. wide, and ¼ in. thick, with a reduced section ¼ in. wide and 0.7 in. long in the center. The percentage elongation of these pieces was determined on a gage length of 0.7 in. (equivalent to 4√A where A equals the original area of the test sample). The results of Greenwood's tests are quoted in Table IV:

*Grant" has remarked: "No failures that could be attributed to lead have been observed, although as much as 6 or 7% lead has not infrequently been found in bearings subjected to severe usage." This is a point of some importance. The fact that alloys such as A.S.T.M. Grades No. 4 and 5 and S.A.E. Specification No. 12, Babbitt, find extensive use fully confirms Grant's observation. However, to use such alloys in the form of thin linings for automotive and aircraft bearings is quite impracticable, not only on account of difficulties of assembly, but also because of their known failure to meet service requirements.

The yield points in the tables below were calculated from the loads at which measurable flow first occurred in the time interval (about 8 sec.) which elapsed

between successive readings of strain.

Greenwood's results show that as the temperature of test rises, the yield points and tensile strengths of most bearing metals fall fairly uniformly, while the percentage elongations and reductions of area increase. However, the ductility temperature curves are less regular than the stress temperature curves. In all the cases examined by Greenwood the temperature coefficient of ductility was greater from 100-175°C. than from room temperature to 100°C.

Homer and Plummer⁴ considered the effect of temperature upon the mechanical properties of test samples most of which had been annealed at 165°C. for one

Fig. 2—Strength temperature curves for tin-base bearing alloys.

week. Some of the alloys containing large amounts of cadmium were treated at 158°C. for 10 days, or at 150°C. for 2 weeks, because they tended to soften and bend at the highest annealing temperature. The object of annealing was to alter the mechanical properties of the alloys from those of the materials as cast to those

which the alloys might be expected to possess after they had been in service for a time sufficient to bring them to structural equilibrium.

The test pieces used were cast to shape, 0.226 in. dia. and 0.884 in. long between the shoulders. Results of the more important tests are shown graphically in Fig. 2. Each graph gives the strength temperature curves obtained from a group of alloys of similar composition. Since frequently two or more alloys in a group have similar properties and the curves are on this account liable to become confused, a different zero on the temperature axis has been used for each curve in each group. In this way the various curves plotted in each figure are spaced out laterally from one another, although they are all drawn to the same scale.

The values for percentage elongation were determined in all cases but, not being concordant, are unsuitable for graphical representation. A general increase in ductility with temperature occurred in all cases, though the increase was slight in some. Above 120°C. some of the high cadmium alloys showed relatively high ductility, while their percentage elongation was small at lower temperatures. Up to 120°C., however, the increase in elongation with temperature was gradual and normal in all cases. The original paper should be consulted for information regarding the Brinell hardness numbers of these alloys at various temperatures and the range of percentage elongation.

Homer and Plummer conclude that the addition of cadmium increases the strength and hardness of the tin-antimony-copper alloys. On the whole, there is a continuous increase of strength with increasing cadmium content, but the extent of the increase becomes progressively less. In most instances there is not much advantage to be gained by adding more than 3% cadmium, particularly as the ductility of the alloys diminishes as their strength increases. It is of particular interest to note that nearly all the alloys lose about the same proportion of their tensile strength on heating through the same range of temperature.

Work must still be done on the effect of copper on the strength of tin-base bearing metals at high temperatures. A consensus of opinion supports the view that increase in copper beyond about 3½% lowers their resistance to certain types of severe service, even though copper does increase both hardness and strength in these alloys. The remarkable behavior, for example, of A.S.T.M. Grade No. 1 in the form of linings (0.02-0.03 in. thick) for connecting rod and crankshaft bearings of automobile and aircraft engines has yet to be logically explained. In this connection it may be noted that "the compressive stress required to cause . . . plastic flow is raised as the ratio of the initial area under compression to the thickness of the metal is increased,"²² an effect that is nicely shown in the following table:

Area and Form of Cross Section of Test Sample, in.	Apparent Limit of Proportionality Under Compression, psi.
$\frac{1}{4} \times \frac{1}{4}$	1,800
$\frac{1}{2} \times \frac{1}{2}$	3,000
1 x 1	3,200

While these results refer to lead, their importance in explaining the increase in strength due to reducing the thickness of babbit in bearings should not be underestimated.

Preparation and Etching of Tin and Tin Alloys for Metallographic Examination

By C. H. Hack*

The preparation of tin and its alloys for metallographic examination requires good technique and care because of the softness and ease of formation of flowed metal on the surface of the specimens. In general, the procedure in preparation is identical to that outlined on page 1556 for lead and lead alloys. The harder alloys are more easily prepared than the softer ones.

The initial surfacing of the specimens may be done by filing or machining on a lathe, using a sharp tool having a sharp rake, followed by grinding on emery papers of decreasing fineness. If a microtome is available, it may be used advantageously in minimizing the amount of subsequent polishing. However, if a microtome is used, a check should be made to see that it possesses three requisite properties as outlined by Vilella, namely: Sufficient rigidity, a properly sharpened knife and such adjustments that cuts of 2 microns in thickness may be made. If a microtome is not available, good success may be had by attaching a microtome knife to the front end of the supporting arm of a milling machine. The specimen is clamped in a vise attached to a slide rest (similar to the type used for a lathe)

Etching Reagents for Tin and Its Alloys

Etching Reagent	Composition	Remarks	Use
No. 1 Nitral	$\{ \text{HNO}_3 \quad 2-5 \text{ ml.}$ $\quad \text{C}_2\text{H}_5\text{OH} \quad 95-98 \text{ ml.}$	Swab or immerse for several minutes	Tin-cadmium or tin-iron alloys
No. 2 Potassium dichromate	Acidified dilute solution		Tin-cadmium alloys
No. 3 Mixed acids in glycerol ¹	A. $\{ \text{HNO}_3 \quad 1 \text{ part}$ $\quad \text{HCl} \quad 1 \text{ part}$ $\quad \text{Glycerol} \quad 8 \text{ parts}$	Immerse $\frac{1}{2}$ -10 min. at 38-42°C.	A. Tin-lead alloys
	B. $\{ \text{HNO}_3 \quad 1 \text{ part}$ $\quad \text{HCl} \quad 3 \text{ parts}$ $\quad \text{Glycerol} \quad 5 \text{ parts}$	Same as for A, above	B. Pure tin
No. 4 Hydrochloric acid	A. HCl (conc)	Immerse for several seconds	To remove surface flow
	B. $\{ \text{HCl} \quad 10-20 \text{ ml.}$ $\quad \text{H}_2\text{O} \quad 90-80 \text{ ml.}$	Immerse $\frac{1}{2}$ -5 min. following A.	Follow A
	C. $\{ \text{HCl} \quad 10 \text{ ml.}$ $\quad \text{H}_2\text{O} \quad 90 \text{ ml.}$	Electrolytic etch at low current density	Tin-iron alloys
No. 5 Ferric chloride	$\{ \text{FeCl}_3 \quad 10 \text{ g.}$ $\quad \text{HCl} \quad 2 \text{ ml.}$ $\quad \text{H}_2\text{O} \quad 95 \text{ ml.}$	Immerse $\frac{1}{2}$ -5 min. at room temperature	Microetching tin-rich Babbitt metal
No. 6 Nitric acid ²	$\{ \text{HNO}_3 \quad 5 \text{ ml.}$ $\quad \text{C}_2\text{H}_5\text{OH (abs)} \quad 95 \text{ ml.}$		Pure tin
No. 7 Picric acid and nitric acid ²	Alcoholic solution		Tin-iron alloys
No. 8 Ammonium polysulphide ³	Concentrated solutions	Immerse 20-30 min. at room temperature	Macroetching of tin-rich babbitt metals
No. 9 Ammonium Persulphate	$\{ (\text{NH}_4)_2\text{S}_2\text{O}_8 \quad 5 \text{ ml.}$ $\quad \text{H}_2\text{O} \quad 95 \text{ ml.}$	Blackens out the tin or tin alloy, leaving the compound as a bright contrasting layer	Tin coatings on steel
No. 10 Acetic Acid	$\{ \text{HC}_2\text{H}_3\text{O}_2 \quad 50 \text{ ml.}$		
	$\quad \text{H}_2\text{O} \quad 50 \text{ ml.}$		
	$\quad \text{H}_2\text{O}_2 \quad 1 \text{ drop}$		soldered joint

Note—Solutions of silver nitrate or 10% nitric acid plus 5% chromic acid are also occasionally used.

mounted to the moving bed plate at a slightly inclined angle. Settings for thin cuts as small as 1 micron may then be made by turning the screw of the slide rest. A final microtoming with cuts from 1-2 microns is preferable for tin and its alloys.

When preparing thin sections, such as tin coatings on metals or thin sections of babbitt linings for metallographic examination, it is generally necessary to mount the section in some molding medium. Wavy materials sometimes used, have a dis-

*National Lead Co., Brooklyn.

advantage, in that they clog the polishing papers and soften in alcoholic etching agents or by solvents used for drying. Likewise, fusible alloys used for mounting, clog the polishing papers, and are usually attacked more readily than the specimen by the etching reagent. 'Acid-hardened bakelite has recently been used for mounting with good success.' The procedure for using this is to add 10 cc. of a bakelite acid-hardening solution to 100 cc. of the bakelite resin, mixing thoroughly. The mixture is then poured into the mold containing the specimen and heated to 40-45°C. when the bakelite begins to harden. It is then further heated at 60°C. for 1-1½ hr. when it sets hard. Bubbling and too rapid hardening may take place if too high a temperature is applied, therefore, it is desirable to use the lower temperature (40°C.) for setting the resin, followed by the application of a higher temperature (60°C.) for hardening. Only sufficient material should be mixed for the immediate work, as the mixture hardens on aging at room temperature. One of the advantages of the acid hardened bakelite is that it does not require high temperatures and pressures.

Polishing—If the specimen has only been given a lathe cut finish, the polishing should start with No. "0" emery paper, followed by successive polishing on No. "00", No. "000" emery paper, all lubricated with paraffin dissolved in kerosene (100 g. of paraffin in 200 ml. kerosene). After polishing on each paper, the specimen should be washed in warm kerosene to remove the grit and paraffin, followed by washing with soap and water to remove the kerosene.³ The specimen may then be etched with HCl (10-20%) or any other suitable etching reagent to remove any metal that may have flowed on the polished surface.⁴ If the specimen has been finished by microtoming, the specimen may be polished on No. "000" emery paper to remove any scratches left by the microtome blade.

In either case, the specimen is then polished on a rotating wheel covered with broadcloth, using a soap solution of levigated alundum grain* (size 600 grain). The solution of soap and levigated alundum grain may be prepared as follows: 5 g. of alundum grain is added to 300 ml. of water. This mixture is thoroughly agitated and allowed to stand for 15 min., when the supernatant suspension is decanted. To this decanted suspension 40 g. of soap are added and the mixture heated until the soap dissolves. As this mixture is nearly solid at room temperature, it is necessary to use it warm. When this polishing medium is poured on to the polishing wheel it forms a gelatinous mass, viscous enough so that it is not thrown off the wheel when driven at 120 r.p.m.⁵ The final steps of preparation consist in polishing on a good grade of silk velvet, using the above polishing medium followed by etching, with subsequent alternate polishings and etchings until the true structure is revealed.¹

Success has been obtained by microtoming, followed by etching rather deeply and then polishing on a polishing wheel covered with silk velvet, using magnesium oxide and water without addition of soap. The specimen is then washed thoroughly in running water, etched and dried. Further light polishings and etchings may be made if necessary. This method has been found to be satisfactory and saves a good deal of time in polishing.

*Finer abrasives such as alumina or magnesium oxide may be used, although these have been reported as giving too much burnishing action, and relief polishing.⁶

Manufacture and Properties of Tin and Tin Alloy Die Castings

By Bruce W. Gonser*

Complete statistics on the production of tin die castings are not available, but in 1937 one company produced over 180,000 lb. for a variety of uses which indicates that there is a fair volume of production.

Manufacturing Characteristics—Tin and alloys of tin used in die casting have a relatively low melting range and are not difficult to handle. They cast easily and rapidly without die injury. The heat to be absorbed is relatively small and severe temperature extremes are not encountered, even though the die may be water cooled, hence 0.20-0.50% carbon steel or cold rolled steel can be used in making dies. For information on dies for die castings see the article in this Handbook, "Composition and Heat Treatment of Dies for Die Castings".

A new die should have some lubrication during the first few days of use. Lard oil is often used, sometimes being sprayed into the die cavity by means of an air hose. Since an oxide film forms over the die with use, lubrication is soon unnecessary. There seems to be no appreciable attack or alloying of the tin with the dies.

In preparing the usual tin-base alloy, the tin is first melted then any required lead, antimony, and copper added, the temperature being kept around 800-900°F. for rapid action. As shown in Table I, the melting ranges vary widely with the composition. The influence of copper is particularly important in this respect, hence particular attention must be given in the case of the high copper alloys to assure a temperature sufficiently high to give a reasonably rapid melting and even distribution of the copper. Such an alloy must be kept well stirred to prevent segregation and, if poured into ingots for later use, cooling should be rapid. Ordinary cast iron pots have been found to be satisfactory for making the tin alloys and for the die casting pot. Fluxes are used in alloying and remelting, such as equal parts of charcoal, powdered rosin and ammonium chloride, but not in the die casting machine. The alloys are invariably made in a separate pot and usually charged to the die casting pot while molten. Finely powdered talc has been used satisfactorily as a mechanical covering over the bath in the machine. It not only prevents excessive oxidation but helps insulate the bath.

When die casting, the temperature is kept safely above the melting range, a compromise being effected between the tendency toward segregation at a comparatively low temperature and the greater dross formation, and cooling necessary at a higher temperature. From 50-100°F. above the liquidus is a fair guide. Even with a safe temperature margin, however, the metal in the casting pot must be kept well stirred to prevent segregation. Low temperature segregation may result in uneven shrinkage and even cracks in the casting.

Pressures used vary widely with the type of machine in operation, as from 200-1,500 psi. with 350 psi. as a fair average. The limit on size of tin-base die castings is usually set at 10 lb., but by far the greatest number weigh less than 1 lb.

Because of the low solidus point, shrinkage of tin-base die castings is slight and dimensional specifications may be closely held. Thus United States Army specifications permit only ± 0.0005 in. per linear in. variation for tin-base die castings compared to double this amount for lead or zinc and ± 0.0025 for aluminum-base die castings. A number of products are consequently die cast from tin alloys where close tolerances are essential. Some speedometer and odometer parts are die cast from a tin alloy with a maximum dimensional variation of ± 0.0002 in. per linear in. Cast threads up to 32 to the in. may be made. Small castings having walls only $\frac{1}{16}$ in. in thickness can be cast.

Tin-base die castings seldom require finishing but they may be easily buffed and coated. Flins and risers are readily clipped since the metal is relatively soft. Self threading screws are frequently used. These alloys machine somewhat like copper in that the tool tends to dig in. Cutting lubricants are unnecessary.

Tin-Base Die Casting Alloys—A great many tin-base alloys have been die cast in the past and, although there has been some tendency to simplify the list, at least a dozen different alloys were specified and made during 1937. Table I gives the compositions and approximate melting ranges of the most important of these alloys, including the 3 A.S.T.M. and 3 S.A.E. standard specifications that fall within

*Metallurgist, Battelle Memorial Institute, Columbus, Ohio.

this field. These standards apply to compositions used because of their bearing properties. It is significant that the 2 most important alloys from the standpoint of recent volume of production (No. 1 and No. 3) do not fall within these standards.

Table I
Tin Alloys Used in Die Casting

Alloy No.	Composition, %			App. Melting Range, °F	
	Tin	Lead	Antimony	Solid	Liquid
1	92	..	5 ½	430	590
2 ¹	91	..	4 ½	433	680
3	90 ½	..	8	435	480
4 ²	86	..	7 ½	460	870
5	83 ½	..	8 ½	464	792
6 ³	82	..	13	460	650
7	79	5	9	440	610
8 ⁴	65	18	15	358	565
9	61 ½	25	10 ½	397	540
10	61	30	6	368	450
11	60	35	5	355	380
12 ⁵	59 ½	26	9.5-11.5

¹A.S.T.M. B-35 T (Tentative Specification) Alloy Grade No. 1; similar to A.S.T.M. B-23 (White Metal Alloys) Grade No. 1; and to S.A.E. No. 10 standard specification. ²Similar to S.A.E. No. 11. ³A.S.T.M. B-35 T Alloy Grade No. 2. ⁴A.S.T.M. B-35 T Alloy Grade No. 3; similar to A.S.T.M. B-23, Grade No. 5. ⁵S.A.E. No. 12.

Permissible impurities according to the A.S.T.M. tentative standards are a maximum of 0.35 Pb, 0.08 Fe, 0.08 As, 0.01 Zn, and 0.01 Al with a maximum of 0.15 As in the case of Alloy Grade No. 3 (No. 8 in Table I). S.A.E. maximum impurities are 0.35 Pb, 0.08 Fe, 0.10 As, 0.08 Bi, no Al or Zn. Permissible variation from the composition of the specified standard, as proposed in the A.S.T.M. specifications, is not over 0.25% for an element present to the amount of 2% or under, 0.50% for elements between 2 and 5%, 0.75% for elements between 5 and 10% and 1% variation for elements over 10%.

Physical Properties—Tests are now in progress under the supervision of the A.S.T.M. to determine the physical properties of the A.S.T.M. standard alloys (No. 2, 6, and 8, Table I). Physical properties of the S.A.E. tin-base Babbitts (No. 2, 4, and 5, Table I) are given under the Handbook Section on Properties of Tin-Base Bearing Alloys.

As a class the tin-base die casting alloys are similar in composition and properties to babbitt metals, although they are not necessarily used as bearings. The tensile strength, hardness, and proportional limit increase, as a general rule, with increasing copper and antimony additions. The tensile strength may vary in this respect from about 10,000-18,000 psi. in the absence of lead. Addition of lead softens the alloy, lowers the melting range. Strength and hardness decrease rather rapidly with increases in temperature, particularly in the case of the alloys containing considerable lead. These alloys are all used to best advantage where strength and impact resistance are not important.

Applications—Most of these die castings are used because of their bearing properties, because of the accurate dimensions to which they can be cast, and in connection with certain types of food handling equipment. In former years most of the production was in casting bearing shells which were inserted in a proper backing; later the babbitt linings were cast directly in a strong metal backing. The wide spread use of centrifugally cast bearings and of other casting means has greatly reduced this field for die casting but many bearings are still made satisfactorily and economically in this way. Quick cooling under pressure in die casting results in a desirable fine-grained structure.

The Zinc Industry

By R. K. Waring*

Zinc Ores—The principal ores are the sulphide, blende; the silicate, willemite; and the oxides, franklinite and zincite. The sulphide is the most widely distributed and is today the principal source of zinc. Sulphide deposits of commercial importance occur in many parts of the world. The only known large deposits of willemite and franklinite are in New Jersey.

Manufacture¹—The sulphide ore is first concentrated usually by flotation. The concentrate is roasted in the presence of air, yielding zinc oxide and sulphur dioxide which is usually converted to sulphuric acid.

Several processes are in use for producing metallic zinc from the roasted ore. The oldest is the horizontal retort process, developed in Belgium about 1806 and first used in the United States in 1859, at Bethlehem, Pa. In this process, ore mixed with coal is charged by hand into small externally fired horizontal retorts. The temperature necessary to reduce the zinc oxide to metallic zinc is above the boiling point of zinc thus producing zinc vapor. Each retort has a condenser attached to it in which the vapor condenses. The molten zinc is tapped at intervals. When the zinc has been largely reduced, the charge is removed. A complete cycle usually takes 24 hr.

In recent years a new process has been developed in which the ore and coal are briquetted and charged into large vertical retorts externally gas fired and built of refractories with good heat conductivity. The charge moves continuously down through the retort and the zinc vapor passes in a continuous stream into a condenser.

The third commercially important method of producing zinc is by the electrolytic process. In this process the roasted ore is dissolved in sulphuric acid. The resulting zinc sulphate solution is purified and the zinc plated out by electrolysis. Very careful control of the purity of the solution is essential to successful operation.

In the retort process the purity of the product depends largely on the impurities in the ore. To a limited extent, the purity of the product can be controlled by initially removing objectionable impurities from the ore. In order to produce zinc of the high purity required for some purposes, however, a refining process has recently been developed in which the impure zinc is subjected to fractional distillation in a rectifying column. A large tonnage of metal containing 99.99+ % zinc is now produced by this process. Zinc of similar purity is also produced by an electrolytic process. In this case the high purity is attained by chemical purification of the zinc sulphate electrolyte.

Grades—The recognized commercial grades of zinc in the United States have been specified by the A.S.T.M.² and are as follows:

	Lead	Iron	Cadmium	Aluminum	Sum of Lead, Iron, Cadmium
(1a) Special High Grade, max., per cent.....	0.007	0.005	0.005	None	0.010
(1) High Grade, max., per cent.....	0.07	0.02	0.07	None	0.10
(2) Intermediate, max., per cent.....	0.20	0.03	0.50	None	0.50
(3) Brass Special, max., per cent.....	0.60	0.03	0.50	None	1.0
(4) Selected, max., per cent.....	0.80	0.04	0.75	None	1.25
(5) Prime Western, max., per cent.....	1.60	0.08

The amount and kind of impurities in the metal have an important influence on the physical and chemical properties of zinc and its alloys.

Uses—The consumption of zinc by uses in the United States for 1936 is given in Table I³.

*Research Division, The New Jersey Zinc Co., Palmerton, Pa.

Table I

Purpose	Tons
Galvanizing (total)	242,000
Sheets	132,000
Tubes	36,000
Wire	30,000
Wire Cloth	6,000
Shapes	38,000
Brass making	168,000
Rolled zinc	55,000
Die castings	72,000
Other purposes	48,000
Total	827,000

Galvanizing, which constitutes the largest use of zinc, is done either by dipping the iron in molten zinc or by electroplating. Hot dip galvanizing is done largely with the less pure grades of zinc. In some cases, such as wire, which must stand bending without flaking of the coating, High Grade or Special High Grade zinc is used. In electrogalvanizing, the zinc may be obtained either from zinc anodes or by direct solution from ore and subsequent purification of the electrolyte. High Grade and Special High Grade zinc are used to a large extent for anodes in the former method. The life of galvanized material is proportional to the thickness of the coating and recent developments in both electrogalvanizing and hot dip galvanizing have been in the direction of applying heavy coatings which will withstand deformation without peeling.

All grades of zinc are used to some extent in brass. The grade used has considerable influence on the properties of the brass. The manufacture and use of brass are discussed elsewhere in this volume.

All grades of zinc from Prime Western to Intermediate are used for rolling. In general, the presence of natural impurities or added metals increase the hardness and stiffness of rolled zinc. Special combinations of lead, iron, and cadmium are used to control the chemical characteristics of zinc for dry batteries and photo-engraving. Rolled zinc is discussed in greater detail in the article on "Wrought Zinc and Zinc Alloys".

The use of zinc-base alloys for die casting has become important in recent years and is increasing rapidly. It is essential for best results to use Special High Grade zinc for this purpose. Zinc die castings are described in a separate article in this volume.

Other forms of zinc include zinc oxide and zinc sulphide, widely used in paint and rubber, and zinc dust, used as a pigment in priming paints for metal.

Constitution of Zinc-Aluminum Alloys

E. A. Anderson,* M. L. Fuller,† and G. Edmunds†

The phase equilibrium diagram of the zinc-aluminum system has been studied intensively. Several excellent papers have recently appeared that offer additional and more accurate data on the location of phase boundaries and one of the papers suggests a modification of the form of the existing diagram. Because of the generally admitted uncertainty of portions of the diagram, it has been considered advisable to reproduce first the diagram based on the work of Hanson and Gayler¹ and of Peirce² and then to report the results of the more recent investigations. This diagram is shown in Fig. 1. The essential form of this diagram agrees with those reported by Tanabe,³ Ishihara,⁴ and Owen and Pickup.⁵

The structure of the beta constituent and the mechanism of its decomposition have been extensively investigated. It is generally agreed that the structure of this phase is crystallographically the same as gamma, that is, a substitutional solid solution of zinc in aluminum. This has been shown by X-ray diffraction studies⁶ of Schwarz and Summa,⁷ Schmid and Wasserman,^{8,9} Owen and Iball,¹⁰ Kennedy,¹¹ Fuller and Wilcox,¹² Kossolapow and Trapeznikow,¹³ and Owen and Pickup.⁵ These papers and others¹⁴ (Meyer,¹⁵ Bugakow,¹⁶ Fraenkel and Scheuer,¹⁷ Fraenkel and Wachsmuth,¹⁸ Imal and Haglya,¹⁹ and Broniewski, Kucharski, and Winawer²⁰) also report upon various phenomena accompanying the transformation and upon the mechanism of the decomposition. Owen and Iball,¹⁰ Owen and Pickup,⁵ and Kossolapow and Trapeznikow¹³ show by X-ray methods that the beta plus gamma region of the diagram is indeed a two-phase region, the two phases having face-centered cubic structures of slightly different lattice dimensions.

Schmid and Wasserman⁸ were unable to determine the solid phase relationships in the region from 0-80% zinc at temperatures above 350°C. They suggest that the peritectic at 443°C. does not exist and that beta and gamma are one phase.

Fink and Willey²¹ have made a careful investigation of the solid alloys from 0-80% zinc at temperatures up to about 400°C. This work was performed by the electrical conductivity and microscopical methods. Fig. 2 reproduces²² the experimental results of Fink and Willey and also the results of Owen and Pickup⁵ and of Schmid and Wasserman.⁸ The several boundaries associated with the peritectic reaction, as shown in Fig. 1, are reproduced in Fig. 2 as dotted lines. The novel feature of the Fink and Willey diagram is the closed field $\beta_1 + \beta_2$, above which the beta and gamma phases are one phase.

This renders unnecessary the concept of a peritectic at 443°C.

Rosenhain and Archbutt,²³ Bauer and Vogel,²⁴ Tanabe,³ and Ishihara⁴ have presented evidence definitely indicating the existence of a peritectic reaction. The work of Owen and Pickup⁵ is in agreement with the existence of a peritectic and suggests that the beta plus gamma region above 360°C. becomes very narrow. This is in good agreement with the work of Tanabe.³ Gayler,²⁵ in discussing the paper of Fink and Willey,²¹ states that she has recently conducted experiments with zinc-aluminum alloys of the highest purity to retest the existence of a peritectic. Thermal analysis by heating and cooling curves demonstrated that a reaction of some kind takes place at 443°C. Gayler's discussion considers several hypothetical diagrams to account for the observed data and states that additional experiments are being

Fig. 1—Zinc-aluminum constitution diagram (Hanson and Gayler-Peirce).

*Chief and †Investigators, Metal Section, Research Division, The New Jersey Zinc Co., Palmerton, Pa.

conducted to redetermine the nature of the diagram in the region of the peritectic. Unfortunately, the results of Gayler's new experiments have not been published up to the present writing. Fink and Willey²² in replying to Gayler's discussion proposed another hypothetical diagram which would be compatible with their experimental results and also with the existence of the peritectic reaction.

Although the central portion of the diagram is in an unsettled state, the terminal solid solution phases have been charted quite carefully. The combined work of Owen and Pickup,²⁰ Schmid and Wasserman,²⁰ and Fink and Willey,²² as represented in Fig. 2, yields data on the solid solubility of zinc in aluminum which are doubtlessly more accurate than the earlier data.^{1, 25, 26, 27, 28} Until the last few years the only careful study on the solid solubility of aluminum in zinc had been that of Peirce.¹ The recent papers are those of Fuller and Wilcox,²⁹ Burkhardt,³⁰ and Auer and Mann.³¹ The data from these sources are given in Table I.

Fig 2—Beta-gamma relationship.

370				1.08
375		0.78		
380			0.8	

^aElectrical conductivity method ^bX-ray diffraction method. ^cMagnetic susceptibility method

The eutectic temperature of 380°C. and the eutectic composition of 5% aluminum remain unchanged from the original work of Rosenhain and Archbutt.³⁴

The eutectoid composition is placed at about 21% aluminum by the work of Hanson and Gayler¹ and that of Tanabe.³ The work of Fink and Willey²² indicates a composition of 22% aluminum for this point. It is interesting to note that the hypothetical compound Al₂Zn₃ has an aluminum content of 21.6%.

The eutectoid temperature has been determined by many investigators. The original determination of Rosenhain and Archbutt³⁴ of 256°C. has been shown to be too low for the reason that too rapid rates of cooling were used in determining the cooling curve through the eutectoid transformation. This was demonstrated in the paper by Fuller and Wilcox²⁹ who worked with heating and cooling curves of various rates and determined that 277°C. was a more probable value for the eutectoid temperature. Fink and Willey²² by electrical conductivity analysis place the temperature at 275°C. The X-ray measurements of Owen and Pickup²⁰ indicate a eutectoid temperature of 272°C. Tanabe³ reported 270°C., and Ishihara⁴ and Jares²³ each reported 280°C.

The crystal structure of the alpha phase is hexagonal close-packed. The lattice dimensions differ from those of pure zinc by reason of the substitution of aluminum

for zinc, the lattice being expanded in a direction parallel to the trigonal axis and contracted in directions perpendicular to this axis.^{11, 12, 13, 14} The gamma phase has the face-centered cubic structure of aluminum, the substituting zinc atoms causing a general lattice contraction. This contraction amounts to 0.00083A per unit cell length per atomic per cent zinc according to Schmid and Wasserman.¹⁰ The beta phase is crystallographically the same as gamma and for a composition of 20.0% aluminum has a unit cell size of 3.991A at room temperature.¹³

The Constitution of Zinc-Cadmium Alloys

E. A. Anderson† and J. L. Rodda††

The zinc-cadmium system is of the simple eutectic type showing solid solubility on both the zinc and cadmium sides.

The liquidus has been determined by numerous investigators, most of the values falling well within 10° variation. The agreement on the eutectic concentration (17.4% Zn) is good, but the temperature values vary between about 260 and 270°C.; 265°C. is probably a fair average.

There is need of a thorough and careful study of the solid solubilities on both sides of the diagram. The divergence of values is shown in Table I for some recent determinations at or near the eutectic temperature.

Table I
Solid Solubilities of Cadmium in Zinc

	Zinc, %	Cadmium, %	Method
Peirce	1.0-2.0 (250°C.)	Electrical conductivity and microscopic
Jenkins	2.0-2.25 (250°C.)	1.75-2.0 (250°C.)	Microscopic
Grube and Burkhardt.....	4.3	3.7	Electrical resistivity
Stockdale	2.95	2.15	Microscopic
Boas	1.8 (250°C.)	X-ray
LeBlanc and Schöpel.....	3.0-4.2	3.4-5.0	Electrical resistivity and microscopic

Since values as low as 0.1% have been reported at 100°C. and room temperature, it is apparent that the solid solubility in zinc drops sharply with temperature. This coupled with insufficient annealing or inadequate quenching may account for the divergence.

With rising temperature above the eutectic, Jenkins and Stockdale agree in showing on the zinc side an increase in solid solubility followed by the normal decrease (a solidus curve reversing with temperature). Their explanation based on an alleged allotropy of zinc is not tenable, however, in view of the abundant evidence against the existence of such allotropes.

Fig. 1 shows our present knowledge of the system.

Recent studies of the eutectic by Zagorodskikh* and by Straumanis and Brakss* show the two phases to have a definite orientation relationship with a strong probability that the basal planes of zinc and cadmium are parallel and that the close packed directions coincide.

The Zinc-Rich Portion of the Zinc-Copper Constitution Diagram

E. A. Anderson* and J. L. Rodda**

The zinc-rich portion of the zinc-copper diagram is shown in Fig. 1. Three recent investigations of the solid solubility of copper in zinc are in substantial agreement. The data of Anderson, Fuller, Wilcox, and Rodda¹⁷ either fall between the values of Hansen and Stenzel¹⁵ and of Burkhardt¹⁸ or close to one or the other.

The peritectic temperature (ϵ + liquid = η) has been determined by numerous investigators,^{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11} all but a few placing it between 423 and 425°C. The agreement in the location of the peritectic point (solid solubility at the peritectic temperature) is not so good. The best agreement is between the work of Shepherd² (2.5%), Hansen and Stenzel¹⁵ (2.66%), and Anderson, Fuller, Wilcox, and Rodda¹⁷ (2.68%).

Determinations below the peritectic point of the liquidus^{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11} are not numerous. The range between the two curves is but a few degrees at the most. The data of Anderson, Fuller, Wilcox, and Rodda¹⁷ have been accepted here.

Various authorities^{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11} largely on the basis of cooling curve data, have placed the intersection of the peritectic horizontal with the liquidus between 1.5% and 2.0% copper. According to Peirce³ primary epsilon was found in chill cast specimens containing 1.81% copper but not in those with 1.5% copper. The value 1.7% copper as plotted in

Fig. 1—The zinc-rich portion of the zinc-copper constitution diagram.

Fig. 1 is the most probable. The course of the liquidus above the peritectic temperature must be considered uncertain by several degrees, since it was determined by cooling curves which are subject to error by undercooling of the melt.

The crystal structure of the eta solid solution and the epsilon phase have both been determined as hexagonal close packed^{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11} with lattice constants as follows:

Phase	A ₀	C ₀	c/a
Pure zinc.....	2.660A	4.938A	1.856
Eta solid solution (1% Cu).....	2.665A	4.896A	1.837
Epsilon (saturated with zinc at 200°C.)....	2.753A	4.290A	1.559

The Widmanstätten structures formed by the segregation of epsilon from eta have been analyzed.¹⁶ The plane of segregation is a {10.4} plane with a strong probability that the conjugate plane of the segregate is also a {10.4} plane.

Constitution of Zinc-Iron Alloys

By E. A. Anderson,* J. L. Rodda,† and G. Edmunds†

The phase boundaries shown in Fig. 1 and 2 are derived principally from the work of Schramm^{2,3,4} and of Truesdale, Wilcox and Rodda⁵ but represent also a careful consideration of older data.

There are five†† well established phases in this system (Fig. 1). A new phase containing 6% iron and formed by a peritectic reaction at 530°C. has recently been proposed (Fig. 2). These phases are tabulated in Table I. To avoid confusion the nomenclature of Schramm and the older designations are both given.

Fig. 1 Zinc-iron constitution diagram

Fig. 2—Zeta phase of the Zinc-iron constitution diagram

Truesdale, Wilcox and Rodda investigated the zinc end of the diagram up to 875°C. The liquidus was determined by direct sampling of the supernatant liquid.

*Chief and †Investigators, Metal Section, Research Division, The New Jersey Zinc Co., Palmerston, Pa.

^{2,3,4}This apparently valuable work covered the determination of several of the phase boundaries on which little or no work had previously been reported. It has also included the first report of the zeta phase. It would be desirable for these determinations to be checked.

††The high temperature body-centered cubic form of iron, delta, is not considered here since its stable region is above the temperatures usually investigated.

Peritectic horizontals were fixed at 672 and 782°C. by heating curves. The solid solubility of iron in zinc was found by microscopic methods to lie between 0.0009 and 0.0028% at temperatures from 150-400°C. A eutectic was noted at about 0.018% iron with a eutectic lowering of less than 0.05°C.

Above a few per cent iron, the preparation of homogeneous and nonporous zinc-iron alloys is difficult. By a unique method of preparing alloys between 4 and 20% iron, Schramm prevented the usual expansion and excessive porosity and produced alloys suitable for microscopic examination. Alloys containing from 20-100% iron were prepared by annealing highly compressed powder mixtures of iron with a zinc-iron alloy containing 15% iron. The need of extremely high temperatures and consequent high pressures to prevent volatilization of zinc was thus avoided. Dense alloys appear to have been produced. Thermal arrests, micrographic, X-ray and magnetic methods were used to investigate the diagram.

The solidus boundaries of the phases Γ ($\text{Fe}_3\text{Zn}_{10}$) and δ (FeZn_7) were determined for the first time by Schramm. The boundaries γ ($\gamma + \Gamma$), γ ($\gamma + \text{liquid}$) and α ($\alpha + \Gamma$) were determined by microscopic analysis, the last boundary being checked by X-ray studies.

Table I
Phases of the Zinc-Iron System

Schramm	Phase Older Designation	Approximate Limits of Composition, % Iron	Crystal Structure	Description
η (eta)	Zinc	0-0.0028	Close packed hexagonal	Zinc with minute amount of iron in solid solution
ζ (zeta)	New	6 ± 0.25	Pattern similar to delta	Formed by peritectic reaction at 530°C.
δ (delta)	FeZn_7	7-11	Hexagonal	Formed by peritectic reaction at 672°C.
Γ (Gamma)	$\text{Fe}_3\text{Zn}_{10}$	20-27	Cubic, 52 atoms to unit cell	Formed by peritectic reaction at 782°C.
γ (gamma)	γ	55-100	Face-centered cubic	Solid solution of zinc in iron
α (alpha)	α	80-100	Body-centered cubic	Solid solution of zinc in iron

The boundaries of an ($\alpha + \gamma$) field have been drawn from meager data. This region needs further study, especially in view of the evidence of Jones²⁴ and of Svechnikov and Gridnev that the temperature of the ($\alpha - \gamma$) transformation is raised by the addition of zinc. The latter claim that no gamma is present in alloys over 17% zinc.

The peritectic temperatures of Schramm, 780 and 668°C. agree with the values of Truesdale, Wilcox and Rodda. A eutectoidal decomposition of γ into ($\alpha + \Gamma$) at 623°C. was demonstrated as indicated by earlier workers. This agrees with the temperature found by Ogawa and Murakami¹² but is about 20°C. lower than the value of Raydt and Tammann.⁶

The temperature of the magnetic transformation was determined by Raydt and Tammann,⁶ Ogawa and Murakami,¹² Fallot,²⁵ and by Schramm.²² It is to be noted that this is not the temperature of the ($\alpha - \gamma$) transformation except in the region between the eutectoid (γ) composition and Γ ($\text{Fe}_3\text{Zn}_{10}$). All agree that the addition of zinc in solid solution lowers the temperature of the magnetic transformation in iron.

The new zeta phase described by Schramm (Fig. 2) has a narrow compositional range near 6% iron and is formed by peritectic reaction at 530°C. between δ (FeZn_7) and melt. The reaction involves a much larger proportion of solid than liquid, is sluggish and may often be almost completely suppressed. The X-ray work has not been reported in detail but the pattern is said to be similar to delta. The formation of this phase may be associated with the high rate of attack of iron by molten zinc observed by Grubitsch²⁷ and others²¹ in the neighborhood of 500°C.

The crystal structures of the phases have been investigated by a number of workers.^{12, 22, 23, 24, 25, 26, 27} The generally accepted structures are given in Table I.

In conclusion it may be stated that the phases present in the system appear to be well established, except that the newly described zeta phase should be confirmed. The nature of the ($\alpha - \gamma$) transformation and the related eutectoidal decomposition need further investigation. The suggestion of Bablík,²⁴ discussed by Jones²⁴ that the appearance or disappearance of some phases may be a function of the pressure during formation, deserves consideration. It is, moreover, obvious

that the extension of the liquidus above about 900°C. is possible only at pressures greater than atmospheric, since otherwise zinc would vaporize. When dealing with alloys above this temperature, it must be kept in mind that the diagram as given represents higher than normal pressures.

Constitution of Zinc-Lead Alloys

E. A. Anderson* and J. L. Rodda†

The equilibrium relations in the zinc-lead system have recently been investigated in detail and the diagram obtained is given in Fig. 1. The system is a simple eutectic type. The relations in the liquid state are complicated by the presence of two liquid phases over a large range of concentration at temperatures ranging from the melting points of the pure metals to those approaching the boiling point of zinc.

Earlier investigations of this system were carried out by Matthiessen and von Bose,¹ Spring and Romanoff,² Wright and Thompson,³ Arnemann,⁴ Heycock and Neville,⁵ Guertler,⁶ Kremann and Knabl,⁷ and Peirce.⁸

Hodge and Heyer,⁹ in a recent investigation of the lead-rich regions, place the eutectic concentration at 99.5% lead and the eutectic temperature at 318°C. Their evidence, based on slowly cooled, but not annealed specimens indicates that the solid solubility of zinc in lead at the eutectic temperature is 0.05%. A microscopic study of zinc-rich alloys in this laboratory¹⁰ indicates that the solid solubility of lead in zinc is definitely less than 0.0019% and possibly below 0.0002%. That a definite, though slight, solubility does exist is evidenced by a growth of the lead particles on annealing.

Hass and Jellinek¹¹ determined the mutual liquid solubility of zinc and lead between 400 and 750°C. by a method in which samples of the liquid were obtained at desired temperatures. The results obtained are in agreement with the results obtained by Waring, Anderson, Springer, and Wilcox¹² at temperatures near the melting point but disagree at higher temperatures.

Waring and associates¹² investigated the zinc-lead system in detail with special reference to liquid solubility. The temperature horizontals for the zinc monotectic and the lead eutectic were placed at 417.8 and 318.2°C., respectively. The liquid solubility curve was established by four different methods and the solubility was found to be higher and the temperature of complete miscibility (790°C.) lower than that reported by any previous investigator. On the basis of rather scanty vapor pressure data, Jellinek and Wannow¹³ have recently questioned these results. The chances of error in the vapor pressure data and in the diagram constructed from these data are considered greater than in the four direct methods of Waring and associates. Waring and Springer¹² have extrapolated the latter data, plotted as $\frac{1}{T}$ against log of the mol fraction of lead in the liquid phase,¹⁴ to the monotectic temperature, fixing the concentration of the monotectic at 0.9% lead. The new method of plotting the data alters slightly the interpolated values originally published. The new values are given below for selected temperatures.

Fig 1—Zinc-lead constitution diagram

Temperature, °C.	% Pb in Zn	% Zn in Pb	Temperature, °C.	% Pb in Zn	% Zn in Pb
417.8	0.9	2.0	650	9	8
450	1.3	2.3	700	15	12
500	2.2	3	750	24	19
550	3.8	4	775	32	26
600	5.6	6	790	Complete miscibility

Constitution of Zinc-Magnesium Alloys

E. A. Anderson* and J. L. Rodda†

The diagram in Fig. 1 of the zinc-magnesium system represents a combination of the data of Hume-Rothery and Rounsefell,¹⁰ Chadwick,¹¹ and Schmid and Seliger.¹²

An intermetallic compound, $MgZn$, (melting point $590^{\circ}C$.) is formed by primary separation from the molten alloys containing 3-46% magnesium. Two additional compounds, $MgZn$ and $MgZn_2$ (Mg_2Zn_3 , according to Laves and St. Werner¹³), are formed through peritectic reactions of $MgZn$, with the melt at $354^{\circ}C$ and $380.5^{\circ}C$, respectively. Solid solution in the compounds $MgZn$ and $MgZn_2$, as claimed by Chadwick¹¹ has been denied by Hume-Rothery and Rounsefell.¹⁰ Botschwar and Welitschko¹⁴ confirm Chadwick's claim.

A new temperature horizontal at about $265^{\circ}C$. was found by Grube and Burkhardt,¹⁵ using electrical resistance measurements. G. Edmunds¹⁶ concludes, after a careful examination of these data, that the diagram between 20-100% magnesium is more complicated than has heretofore been indicated and that a eutectoid inversion probably occurs in most of these alloys at about $265^{\circ}C$. Microstructural examinations of alloys in this region have confirmed this discovery, but no extensive investigation has been made which would definitely establish this portion of the diagram.

Schmid and Seliger,¹² using X-ray measurements of lattice constants, have determined the following values for the solid solubility of zinc in magnesium.

Temperature, $^{\circ}C$	340*	300	250	200	150
% Zinc	8.4	6.0	3.3	2.0	1.7

*Eutectic temperature.

Fig. 1—Zinc-magnesium constitution diagram.

Hansen,¹⁰ in his review of the system, considers these determinations to be the most reliable.

Evidence of a limited solid solubility (approximately 0.1% at $360^{\circ}C$.) of magnesium in zinc has been found by Chadwick¹¹ and Hume-Rothery and Rounsefell.¹⁰ Unpublished data from the authors' laboratory indicate that this falls off to less than 0.002% at room temperature.

Friauf¹⁷ and Tarschisch¹⁸ have investigated the crystal structure of the compound $MgZn$, and found it to be hexagonal. Friauf's parameter values are as follows: $a = 5.15A$, $c = 8.48A$, $c/a = 1.64$.

The compounds $MgZn$ and $MgZn_2$ are both considered by Tarschisch¹⁸ to be hexagonal, McKeehan¹⁹ concludes, after an analysis of Tarschisch's work that these structures require more experimental verification before they can be regarded as established.

Edmunds and Fuller²⁰ have determined the structure of $MgZn$, as a body-centered cube, with 52 atoms in the unit cell, in which $a = 9.44A$. Laves and St. Werner consider the compound to be Mg_2Zn_3 , with a simple cubic lattice containing 38 or 39 atoms and a cell dimension of $a = 8.29A$.

The Zinc-Rich Portion of the Zinc-Manganese Constitution Diagram

E. A. Anderson* and J. L. Roddat†

The zinc-manganese system has been studied up to about 40% manganese. The data are in such marked disagreement, however, that this summary will be limited to alloys of not over 2% manganese. Those interested in higher manganese contents are referred to the comprehensive review of Hansen.³

The zinc end of the diagram shows a limited solid solubility of manganese in zinc and a slight depression of the melting point to form a eutectic. The solid solubility at the eutectic temperature has been variously placed between 0.5 and 1% manganese^{1, 2, 3, 4} and the eutectic concentration between 0.6 and 2.0% manganese.^{1, 2, 3, 4} The respective values of 0.5 and 1% manganese seem most probable. The solid solubility has been shown to decrease with temperature to a value near 0.1% at room temperature.²

The diagram shown in Fig. 1 is taken from Peirce's investigation.²

The High Zinc Portion of the Zinc-Nickel Constitution Diagram

E. A. Anderson* and J. L. Roddat†

Most of the experimental work done on the zinc-nickel system has dealt primarily with the determination of the limits of the several intermediate phases. Only a few investigators have concerned themselves with the zinc-rich solid solution.

The early work on the nickel-zinc system was thoroughly reviewed by Tafel¹ in 1908. Chiefly on the basis of thermal analysis, with some microscopical data, he concluded that a eutectic horizontal exists at 418.5°C., the eutectic concentration being about 0.25% nickel.

Two investigations of the solid solubility boundary for the zinc-rich end of the system have been carried out. In the second of these investigations, the location of the eutectic horizontal at 418.5°C. was confirmed.

In 1922, Peirce² concluded that the eutectic point must lie between 0.12 and 0.25% nickel. He noted at the time a structural association of the nickel-zinc eutectic with the lead-zinc monotectic which may have some bearing on this portion of the zinc-nickel system. From microscopical studies and electrical resistivity measurements, Peirce concluded that the solid solubility at room temperature is less than 0.034% nickel and that the solubility increases with increasing temperature to a value of not over 0.1% nickel.

In 1933, Heike, Schramm, and Vaupel³ conducted an investigation on vacuum-melted alloys very carefully homogenized and brought to equilibrium. On a basis of microscopical examination, these workers placed the eutectic at 0.25% nickel. They found the solid solubility of nickel in zinc to be 0.05%, independent of the temperature. The X-ray methods employed by Caglioti⁴ were unable to detect any solubility of nickel in the zinc lattice.

Fig. 1 and 2 show the zinc-rich portion of the zinc-nickel system according to Peirce and according to Heike, Schramm, and Vaupel.

While the main essentials of this portion of the diagram seem to be clearly defined, there seems to be necessity for further work, preferably with purer materials, if the exact locations of the eutectic and of the solid solubility boundary are to be determined.

Fig. 1—Solid solubility of nickel in zinc according to Peirce.

Fig. 2—Solid solubility of nickel in zinc according to Heike, Schramm and Vaupel.

The Constitution of the Silver-Zinc Alloys

By E. A. Anderson* and J. L. Rodda†

The diagram shown in Fig. 1 is essentially that given in Hansen's comprehensive review,¹⁰ but has been modified slightly to fit more recent data. Hansen's diagram is based on the following principal sources of data:

Heycock and Neville¹: Liquidus

G. J. Petrenko², Ueno³: Liquidus, solidus, temperatures of peritectic reactions ($\alpha + \text{melt} \rightleftharpoons \beta$, $\gamma + \text{melt} \rightleftharpoons \epsilon$, $\epsilon + \text{melt} \rightleftharpoons \eta$), β transformation.

Carpenter and Whiteley⁴: Solubility boundaries, temperatures of peritectic reactions ($\alpha + \text{melt} \rightleftharpoons \beta$, $\gamma + \text{melt} \rightleftharpoons \epsilon$, $\epsilon + \text{melt} \rightleftharpoons \eta$).

G. J. Petrenko and B. G. Petrenko⁵: Temperature and extent of the peritectic reaction, $\beta + \text{melt} \rightleftharpoons \gamma$. A somewhat questionable transformation at 228°C. in the ($\zeta + \gamma$) field.

More recently Hume-Rothery, Mabbott and Evans¹⁴ have determined the alpha solidus by quenching experiments and these data have been used in Fig. 1. The X-ray determinations of phase boundaries by Owen and Edmunds¹⁵ have been indicated in the figure but it is to be doubted whether they attained equilibrium, in view of the short annealing times employed.

The resemblance of the silver-zinc system to that of copper-zinc has been frequently noted. X-ray structural studies of the beta silver-zinc alloys have been an aid in interpreting the beta copper-zinc structures. The transformation in beta silver-zinc alloys has recently been clarified by Straumanis and Weerts¹¹ and by Weerts.¹² Above the transformation temperature, the phase is body-centered cubic with a random distribution of silver and zinc atoms. Quenched specimens β' show the same structure with an ordered arrangement of atoms. This β' phase is, however, in a metastable condition. The stable phase is zeta (ζ) which Westgren¹ has found to be hexagonal. Zeta is formed by slow cooling through the transformation temperature or by the annealing or drastic cold working of β' below this temperature.¹¹

Several investigators have claimed a high solid solubility of silver in zinc. Owen and Edmunds¹⁵ value at 408°C. is 9.0% silver. From a study of microscopic specimens, Wilcox and Rodda¹⁷ believe the solubility to be less than 5% silver at 400°C. and approximately 3% silver at 300°C.

Smith¹³ has investigated the mechanism of the segregation of alpha from beta along the sloping ($\alpha + \beta$) - β boundary. Weerts¹² investigated the similar separation of gamma from beta and the transformation of beta into zeta. In all cases, the new phase was found to bear an orientation relationship to the parent crystal.

Westgren and Phragmén⁴ as well as others^{1, 18, 19} have investigated the crystal structures of the various phases. The phase structures are tabulated below:

Fig. 1—Silver-zinc constitution diagram

*Chief and †Investigator, Metal Section, Research Division, The New Jersey Zinc Co., Palmerton, Pa.

Phase	Structure	Atoms Per Unit Cell
α	Face-centered cubic	4
β	Body-centered cubic	2
ζ	Hexagonal	9
γ	Cubic	52
ϵ	Close-packed hexagonal	2
η	Close-packed hexagonal	2

The approximate axial ratios of the epsilon and eta phases are 1.56 and 1.8, respectively, varying slightly with composition. According to Weerts,¹¹ 0.367 is the axial ratio of the zeta phase.

Constitution of Zinc-Tin Alloys

E. A. Anderson* and J. L. Rodda†

The zinc-tin system is of the eutectic type with no evidence of solid solubility on the zinc side and nonconcordant indications of some solubility on the tin side.

The present diagram is substantially as found by earlier workers.^{1, 2, 3, 4, 5} The liquidus values determined by cooling curves are in substantial agreement. Before final acceptance, however, they should be checked by an alternative method. The eutectic temperature and concentration lie between 198-199°C. and 7.5-9.5% tin, respectively. After an inspection of the data, Hansen¹⁴ chose the values 199°C. and 9% tin as the most probable.

Saldau¹¹ placed the solid solubility of zinc in tin between 0.5 and 1.5% at 185°C. These results are to be questioned in view of his observation of two polymorphic changes in the zinc used in the investigation. This is quite contrary to the findings of present day metallurgists and would indicate that the zinc used by Saldau was of an impure grade. More recently Blondel and Laffitte¹² have claimed a solid solubility of 2.5% zinc.

Fig. 1—Zinc-tin constitution diagram.

Peirce⁷ placed the solid solubility of tin in zinc below 0.05%. Tammann and Rocha¹³ claim the limit to lie between 0.05 and 0.1% tin. Definite effects of tin on the hot shortness of zinc have been observed in this laboratory at substantially less than 0.05% tin. If any solid solubility exists it must be less than 0.05% tin.

Physical Constants of Zinc

By E. A. Anderson* and J. H. Craig†

Introduction—Zinc of 99.99+ % purity has been produced commercially for several years. The principal impurities are lead, cadmium, and iron. "Spectrographically pure" zinc has been produced in laboratory quantities by the vacuum distillation of high grade zinc and has been used for the determination of some physical constants.

Atomic Weight—Zinc has the atomic number 30. According to the 1939 International Table of Atomic Weights, the atomic weight of zinc is 65.38. F. W. Aston¹ reports that the isotopes of zinc are as follows, listed in the order of decreasing abundance: 64, 66, 68, 67, 65, 70, and 69. The existence of isotopes 65 and 69 is doubted, however, by K. T. Bainbridge.²

Crystal Structure—Zinc has the hexagonal close-packed atomic arrangement and has the symmetry of space group D_{6h} .³ The unit cell dimensions of the crystal lattice are $a_0 = 2.6600 \pm 0.0002\text{Å}$, $c_0 = 4.9379 \pm 0.0005\text{Å}$ and $c/a = 1.8563$ at 27°C. according to M. L. Fuller who worked with filings of 99.99+ % pure zinc. Jette and Foote, working with spectrographically pure zinc, report $a_0 = 2.6597\text{Å}$, $c_0 = 4.9367\text{Å}$ and $c/a = 1.8561$ at 25°C.

If the atomic domain of the zinc atom is considered as a prolate spheroid, it would have an equatorial radius of 1.3300Å and an axial radius of 1.5117Å at 27°C. The density calculated from the crystal structure data is 7.126 g. per cc. at 27°C.

Zinc exhibits no allotropy. Four papers which have appeared in the last decade have shown that only one crystal form exists from room temperature to the melting point. Peirce, Anderson and Van Dyck,⁴ Freeman, Sillers and Brandt,⁵ and Simon and Vohsen⁶ used the X-ray diffraction method and Anastasiadis and Guertler⁷ used the method of thermal analysis.

Specific Gravity—Chemical composition and physical state affect the specific gravity of zinc. Typical data from various investigators follow:

Type and Purity of Zinc	Temperature, °C.	D (g./cc.)
Molten, 99.94% pure.....	419.4	6.92 (3)
Cast, 99.993% pure.....	25	7.131 (6)
Rolled, 99.993% pure.....	25	7.142 (3)
Swaged, S.F. wire, 0.07 in. dia.....	25	7.133 (10)

The best values for general use seem to be 7.13 for cast zinc and 7.14 for rolled zinc.

Compressibility of Single Crystals—The determination of compressibility of zinc single crystals by P. W. Bridgman⁸ yielded the following values at 30°C.:

$$\begin{aligned}
 90^\circ \text{ Orientation} &= -\frac{\Delta l}{l_0} = 1.57 \times 10^{-11} p - 0.75 \times 10^{-13} p^2 \\
 0^\circ \text{ Orientation} &= -\frac{\Delta l}{l_0} = 13.50 \times 10^{-11} p - 7.68 \times 10^{-13} p^2 \\
 \text{Volume Compression} &= -\frac{\Delta V}{V_0} = 16.64 \times 10^{-11} p - 9.62 \times 10^{-13} p^2
 \end{aligned}$$

where p is in kg. per sq. cm.

Coefficient of Thermal Expansion—The thermal expansions of single crystals of zinc of high purity have been reported by several investigators. The determinations were made at various angles to the principal axis as shown in the following tabulation:

Grade of Zinc	Form	Orientation	Temperature, °C.	Coefficient $\times 10^4$
Spectrographically pure	Rod, 2.5 mm. in dia.	44° to the principal axis	0-50	4.00 (12)
			0-100	4.04
			0-150	4.23

*Chief Investigator, †Investigator, Metal Section, Research Div., The New Jersey Zinc Co., Palmerton, Pa.

Kahlbaum's Best (0.014% Pb, 0.012% Cd)	Rod, 2.5 mm. in dia.	Parallel to the principal axis	0-50	5.48	(12)
			0-100	5.70	
			0-150	5.74	
			0-200	5.80	
			0-250	5.81	
			0-300	5.73	
Kahlbaum's Best	Rod, 2.5 mm. to 2.2 cm. in dia.	Parallel to hexagonal axis	18	5.74	(13)
		Perpendicular to hexagonal axis	18	1.26	

On polycrystalline cast rods, 30 cm. x 0.714 cm., of 99.993% pure zinc, the Bureau of Standards¹⁰ gives the following values:

Temperature, °C.	Coefficient
20-100	3.95×10^{-5}
20-150	3.96×10^{-5}
20-200	3.97×10^{-5}
20-250	3.97×10^{-5}

The International Critical Tables give the following data on the thermal expansion of zinc:

Temperature, °C.	Coefficient
-170-60	29.5×10^{-6}
0-300	35.4×10^{-6}

Other values found in the literature, as summarized by Burkhardt,¹⁴ range from 17.1×10^{-6} to 36.4×10^{-6} . The wide variation of these results was probably caused, in part, by differences in orientation.

The following data on hot rolled zinc (99.94% pure) were obtained¹ in the range of 20-40°C.:

Direction of Test	Linear Coefficient of Expansion
With Grain	0.0000325 per °C. (0.000018 per °F.)
Across Grain	0.000023 per °C. (0.000013 per °F.)

The coefficient of cubical expansion is given in the Smithsonian Physical Tables as 89.25×10^{-6} per °C. between 0° and 100°C.

For other values on thermal expansion, see the work of Owen and Iball,¹⁵ Owen and Yates,¹⁶ Grüneisen and Goens,¹⁷ and McLennan and Monkman.¹⁸

Melting Point—The melting point of 99.94% pure zinc has been determined¹ as 419.4°C., while Roeser and Wensel¹⁹ give a temperature of 419.48°C. for metal 99.993% pure. On spectrographically pure zinc, a melting point of 419.45°C. has been obtained by the authors and 419.47°C. at the Bureau of Standards.¹⁰

Specific Heat—Determinations of specific heat by various investigators are shown in the following table:

Wüst ²⁰		Eastman, Williams and Young ²¹		Awbery and Griffiths ²²		Umino ²³	
Temp., °C.	Specific Heat	Temp., °C.	Specific Heat	Temp., °C.	Specific Heat	Temp., °C.	Specific Heat
0	0.0875	100	0.095	100-200	0.099	50	0.0940
						100	0.0946
100	0.0965	200	0.100	200-300	0.105	200	0.0981
						300	0.0981
200	0.1052	300	0.104	300-400	0.118	400	0.1002
						500	0.1022
300	0.1139	400	0.109	420-500	0.092	600	0.1473
						700	0.1444
400	0.1226					800	0.1423

Umino gave the purity of his zinc as 99.948%. No mention of purity was made by the other investigators.

For other data on specific heat at various temperatures, see Behrens and Drucker,²⁶ Keesom and van den Ende and Clusius and Harteck.²⁷

Latent Heats of Fusion, Vaporization, Sublimation—In a critical review of the literature, C. G. Maier²⁷ gives the following equations for the latent heats of fusion, vaporization, and sublimation:

Heat of Fusion

$$\Delta H_f = 685 + 1.80T - 0.745 \times 10^{-3}T^2$$

Heat of Vaporization

$$\Delta H_v = 31087 - 2.09T - 0.575 \times 10^{-3}T^2$$

Heat of Sublimation

$$\Delta H_s = 31772 - 0.29T - 1.32 \times 10^{-3}T^2$$

where ΔH_f = cal. per g. atom and T = absolute temperature.

The values derived from the foregoing equations are the most reliable obtainable. The latent heat of fusion thus obtained is 24.09 cal. per g. at 419.45°C. The latent heat of vaporization is 425.6 cal. per g. at 905.4°C.

Boiling Point and Vapor Pressure—The following values for the boiling point of zinc have been reported: C. G. Maier²⁸ 905 ± 2°C. and Bauer and Brunner²⁹ 907°C.

C. G. Maier²⁸ of the United States Bureau of Mines has given the following formula for the vapor pressure of zinc:

$$\log P = 12.0013 - \frac{6670}{T} - 1.1265 \log T$$

where P = pressure in mm. of mercury and T = absolute temperature.

Thermal Conductivity—Bidwell and Lewis,³⁰ working with a single crystal of 99.993% pure zinc, report the following values:

Temperature, °C.	Thermal Conductivity Cal. Per Sec. Per Sq. cm. Per cm. Per °C.
-200	0.36
-150	0.34
-100	0.33
-50	0.32
0	0.30
50	0.29
100	0.28

The orientation of the single crystal with respect to the direction of measurement was not stated.

Goens and Grüneisen³¹ determined the thermal conductivity of a single crystal of zinc (purity not mentioned) both parallel to and perpendicular to the hexagonal axis. Their results follow:

Temperature, °C.	Thermal Conductivity	
	Parallel to Hexagonal Axis	Perpendicular to Hexagonal Axis
-252	1.69	1.35
-190	0.316	0.328
20	0.296	0.296

Bidwell and Lewis³⁰ and Bailey³² worked with polycrystalline zinc. The first mentioned investigators used rods of 99.993% pure zinc, cast in vacuo and also in air. Bailey used rods, 0.585 cm in dia., 7-8 cm. long, turned from larger rods, of pure redistilled zinc. Their results follow:

Bidwell and Lewis			Bailey	
Temperature, °C.	Thermal Conductivity		Temperature, °C.	Thermal Conductivity
	Cast in Vacuo	Cast in Air		
-200	0.33	0.31	136	0.265
-150	0.31	0.29	153	0.257
-100	0.29	0.28	176	0.257
-50	0.28	0.27	206	0.249
0	0.27	0.26	279	0.244
50	0.26	0.25	282	0.241
100	0.26	0.24	313	0.237
150	0.25		367	0.238

The effect of magnetic fields on the thermal conductivity of zinc was investigated by H. M. Brown.²² He found that a longitudinal field of 10,000 gauss produced no change in the thermal conductivity of zinc at 0°C. which was reported as 0.280 cal. per sq. cm. per cm. per second per °C.

Heat of Combustion—C. G. Maier²³ reviewed the status of investigations on the heat of formation of zinc oxide and reported new experimental work that indicated definitive values. For dry oxide and wet oxide the values were ΔH_{ox} = -83156 and -83200, respectively. The free energy of formation of the oxide from cell measurements was shown to be $\Delta^{\circ}F_{\text{ox}}$ = -75930 and the value calculated from entropies was -75979. The agreement was thought to be well within the estimated probable error of the calorimetric work on zinc oxide (about 50 calories).

Optical Properties—The reflection of light rays from zinc is, of course, a function of the condition of the surface of the specimen. Provostaye and Desains²⁴ state that 68% of normally incident white light is reflected by zinc. Drude²⁵ found that 77% of red light is reflected. In neither case is the condition of the surface specified.

The Smithsonian Physical Tables state that the total radiation from an oxidized zinc surface is 0.110 as compared with a black body at 1.00.

Burkhardt²⁶ quotes the following data from Coblenz²⁷ on the relationship of reflection and wave length:

Wave length in microns.....	188	200	251	305	357
Reflection in %.....	17	22	39	48	51

Coblenz²⁷ also found that the reflectivity of a polished zinc surface goes through a minimum at 1 micron, rising immediately and reaching a peak value beyond 2 microns.

Electrical Properties—A number of investigators have reported data on the electrical resistivity of zinc single crystals. The following table gives some characteristic data.

Investigator	Type of Zinc Used	Temperature, °C.	Electrical Resistivity (Ohms per cm. ³)	
			Parallel to Hexagonal Axis	Perpendicular to Hexagonal Axis
Tyndall and Hoyem ²⁸	S.P.	20	6.16×10^{-6}	5.83×10^{-6}
Tyndall and Hoyem ²⁸	Kahlbaum's Best	20	6.20×10^{-6}	5.86×10^{-6}
Bridgman ²⁹	Kahlbaum's Best	20	6.06×10^{-6}	5.83×10^{-6}
Way ³⁰	99.99+	20	6.170×10^{-6}	5.842×10^{-6}
Poppy ³¹	99.99+	20	6.161×10^{-6}	5.842×10^{-6}

The Bureau of Standards,³² working with polycrystalline spectrographically pure zinc wire swaged to 0.07 in. dia., obtained a value of 5.916×10^{-6} ohms per cm.³ at 20°C.

The temperature coefficient of resistivity of a single crystal of spectrographically pure zinc was determined by Hoyem³³ as 4.058×10^{-4} . This is an average value for a temperature range of -170°C.-25°C. and includes measurements made at angles from 1°-86.5° to the hexagonal axis. Spectrographically pure zinc wire, swaged to 0.07 in. dia. and drawn to 0.0089 in., was found by the Bureau of Standards³² to have a temperature coefficient of resistivity of 4.19×10^{-4} in the range 0°-100°C.

The electrical conductivity of rolled zinc varies with the composition and rolling treatment. Determinations made at 20°C. by The New Jersey Zinc Co.³ on specimens cut parallel to the rolling direction are given below:

Type of Zinc	Treatment	Electrical Conductivity	
		Mhos $\times 10^4$	Relative (Cu = 100)
99.94% pure	Hot rolled	18.50	28.44
99.94% pure	Cold rolled	18.40	28.27
1.1% Pb, 0.05% Cd	Hot rolled	18.34	28.17
1.1% Pb, 0.05% Cd	Cold rolled	18.28	28.06

Electrochemical Equivalent—The 1933 Smithsonian Tables give the electrochemical equivalent as 1.21950 g. per ampere hour.

Electrolytic Solution Potential—The single electrode potential of zinc in a solution of normal metal ion concentration is given as -0.7581 by Lewis and Randall^{4a} and as -0.76 by Blum and Hogaboom.^{4b} These values are based on the normal hydrogen electrode as zero and are calculated from measurements made on dilute solutions in which the metal ion concentrations are measured.

Thermoelectromotive Force—The Bureau of Standards¹⁰ have determined the thermal emf. of spectroscopically pure zinc against pure No. 27 platinum wire. The spectroscopically pure zinc was swaged to 0.07 in. dia. and then cold drawn to 0.0365 in. The cold junction was at 0°C. and the emf. given below is that developed at the temperature of the hot junction.

Temperature, °C.	Emf. (Millivolts)	Temperature, °C.	Emf. (Millivolts)
0	0.000	250	2.610
50	0.331	300	3.417
100	0.758	350	4.310
150	1.276	400	5.290
200	1.894	415	5.604

Magnetic Susceptibility—McLennan, Ruedy, and Cohen⁴ give the following data on the magnetic susceptibility of zinc single crystals: Parallel to hexagonal axis = -1.90×10^{-7} ; perpendicular to hexagonal axis = -1.45×10^{-7} .

Work in the authors' laboratory⁸ on polycrystalline specimens, 99.94% pure, shows that in the as cast condition the magnetic susceptibility is about -8.36×10^{-7} while annealing at 375°C. for 20 hr. raises this value to about -1.2×10^{-6} .

Supra Conductivity—The resistance of zinc vanishes at 0.79° absolute, according to the work of W. G. Keesom⁴ as summarized in Chemical Abstracts. The zinc used was high purity metal obtained from the Bureau of Standards. While not stated in the Abstract, it is probable that the zinc was of 99.993% purity and was tested in the cast form.

Transmission of Sound—The velocity of sound in zinc has been determined by Masson⁴ as 3,700 meters per sec. (16,140 ft. per sec.). The velocity of sound in air is 332 meters per sec. While no specific statement is made, the above data probably refer to cast zinc at room temperature.

Surface Tension—The Bureau of Standards¹⁰ have tabulated the following values from various sources:

Temperature, °C.	Capillary Constant ^a A ² — mm. ³	Surface Tension Dynes per cm.	Sources
450	...	755 ^b	Hogness
477	23.5	753	Hogness
500	...	751 ^b	Hogness
543	23.6	747	Hogness
590	24.54	707.5 ^c	Smith
600	24.99	787 ^d	Bircumshaw
700	24.63	763	Bircumshaw

^aA² = radius of capillary tube \times height.

^bCalculated by means of equation $r = 758 - 0.090(t-419)$

^cMean value 580-630°C.

^dZinc used contained 0.035 Cd, 0.008 Fe, 0.006 Pb, trace Cu.

Properties of Wrought Zinc and Zinc Alloys

By E. H. Kelton*

General—Wrought zinc and zinc alloys may be obtained in the form of rolled strip and sheet and drawn rod and wire. Wrought zinc has desirable corrosion resistant properties for many types of service, and as corrosion products that may form are colorless, they do not stain other materials. Wrought zinc has chemical characteristics particularly adapted to certain uses such as dry batteries and offers combinations of desirable physical and mechanical properties at relatively low cost. Practically all commercial wrought zinc contains small amounts of natural impurities, mainly lead, iron, and cadmium (see the article on "Zinc Industry", Table I), while the present commercial alloys usually contain additions of copper up to about 1% and sometimes smaller amounts of other elements.

Rolled Zinc—By far the commonest forms of wrought zinc are rolled strip and sheet. Rolled zinc may be fabricated by drawing, forming, stamping, bending, or spinning. Practically all of the companies which market rolled zinc produce a grade which approaches "Intermediate" in analysis and one or more others of higher or lower purity. The classifications used in Table I are arbitrary. The analyses shown are typical ones covering the range and do not necessarily include every variation found among the grades produced by the various companies. Each grade listed is representative of one of what may be termed the standard types produced by practically all zinc rollers. In addition, many producers market special grades which are intermediate to those listed and usually produced to meet a special class of business.

Drawn Rod and Wire—Zinc and zinc alloy rod and wire are produced from rolled or extruded rods afterwards drawn to the desired sizes in much the same manner as brass. There is no wide use for zinc in this form at present but comparatively small quantities are produced for use in spray metal coating, and, in small sizes, for weaving into brake linings.

Mechanical Properties—In the testing of zinc and zinc alloys, it is essential to control closely the testing temperature and speed. The values listed in Table II were obtained at tensile speeds of $\frac{1}{4}$ in. per min. head speed on 2 in. gage lengths at a temperature of 70-80°F.

The tensile strength values shown in Table II may be used in calculating the effect of intermittent loads. Due to the fact that creep is encountered in zinc at room temperature at loads well below the ultimate strength, entirely different data must be used in dealing with continuous loads. In general, the purer the zinc and the higher the service temperature, the lower the resistance to creep. Suppliers should be consulted for data applicable to particular problems where continuous loads are involved. For instance, 10,000 psi. is the figure usually used as the static strength of a zinc alloy used for roofing and rolled especially for highest static tensile strength. Designing on this basis rather than using a tensile strength of, say 35,000 psi., insures against unsightly sagging of the sheets under static roofing loads.

No true elastic limit can be determined by ordinary methods because of the creep phenomenon. The necessity for controlling the speed and temperature of testing is due to the same cause.

Fabrication of Rolled Zinc and Zinc Alloys—All severe fabricating operations should be carried out at temperatures above 70°F. Warm soapy water (using a neutral soap to avoid staining) is the cheapest lubricant available and is as satisfactory as any.

Rolled zinc and zinc alloys of the proper grades are readily drawn into a great variety of articles such as battery cups, eyelets, meter cases, vanity cases, flashlight reflectors, and fruit jar caps. They are just as readily rolled or press formed, stamped, or spun into a wide variety of items such as addressing machine plates, buckles, ferrules, cans, cases, ornaments, name plates, gaskets, weatherstripping, or lamps.

Deep Drawing—In the deep drawing of rolled zinc and zinc alloys the following points should be observed:

The reduction in diameter from blank to first cup should not exceed 40%. The

*Research Division, New Jersey Zinc Co., Palmerton, Pa.

Table I
Classification of Wrought Zinc

Grades	Pb	Fe, Max.	Composition, %			Zn	Characteristics	Suggested Uses
			Cd	Cu	Mg			
a	0.05 max.	0.010	0.005 max.	0.001 max.		Balance	Provides max. softness and ductility. Self annealing at room temp.	Spinning trade.
b	0.05-0.12	0.012	0.005 max.	0.001 max.		Balance	High ductility with low stiffness. Uniform corrosion characteristics in dry cells. Susceptible to almost no work hardening.	Battery cans, fuses, drawn and formed articles.
c	0.30-0.65	0.020	0.20-0.35	0.005 max.		Balance	Stiffness and good ductility. Uniform corrosion characteristics in dry cells. Uniform etching qualities. Capable of some work hardening.	Battery cans, photoengravers' sheet, boiler and ship plates, weatherstrip.
d	0.05-0.12	0.012	0.005 max.	0.65-1.25		Balance	High stiffness and hardness. Good ductility. Better creep resistance than Grade C. Can be work hardened.	Weatherstrip, grommets, drawn and formed articles requiring stiffness.
e	0.05-0.12	0.015	0.005 max.	0.75-1.25	0.007-0.02	Balance	Max. hardness, stiffness, and creep resistance. Excellent work hardening properties. Requires special fabricating technique.	Corrugated roofing, articles requiring max. stiffness.

reduction in diameter of succeeding cups should not exceed 20% unless holding sleeves on the draw punches, or their equivalents are used.

In general, radical clearance between the punch and die on the first draw should equal the thickness of the stock. On succeeding draws the clearance should be cut down to pinch the metal slightly.

The softer grades of rolled zinc are self annealing at the temperatures developed during drawing, and hence no annealing is required between operations. The harder grades work harden somewhat and may require annealing if there are a large number of redrawing operations. Annealing at temperatures slightly above 212°F. is usually sufficient.

Table II
Mechanical Properties of Wrought Zinc and Zinc Alloys

Composition, %	Rolling Treatment	Scleroscope Hardness	With Grain ¹	
			Ultimate Tensile Strength, Psi	Elongation in 2 In., %
Pb 0.05 max.	All	13-15	16,000-19,000	40-70

Mg 0-0.025				

¹Across grain tensile values average roughly 20% higher than the with grain values in strip rolled metal. The elongations are correspondingly lower.

The properties in Table II are the average limiting values to be secured by ordinary sheet or strip rolling methods. The wide ranges of values are secured by varying the analysis of the metal, the rolling treatments and, except in the case of the hardness, the direction of testing.

Some of the rolled zinc alloys have very marked work hardening characteristics and require annealing at temperatures of 400-500°F. to carry out a series of redrawing operations successfully. For instance, a certain article may require a cupping operation followed by four redrawing operations. If the cupping operation involves a 42% take-in and the redraws 15-20% take-ins, the cups may start to split at the tops on the third redraw. It is usually more economical to anneal the second redraw cups than to redesign the tools to lighter take-ins and add another redrawing operation. In this annealing, it is only necessary to bring the cups to the required temperature, but it is customary to leave them in the furnace for several hours to insure that all of the cups reach the desired temperature. It may be necessary to exert some care to prevent extremely coarse recrystallization and consequent weakening of the sections of the cup which have not been severely worked. These details must be worked out separately for each article and each alloy, but coarse crystal growth can generally be prevented by utilizing the lowest practicable annealing temperature and spreading out the cups so that the shortest possible annealing time can be employed.

Soldering—Rolled zinc and zinc alloys are easily soldered by conventional methods. The usual precautions regarding proper cleaning and fluxing should be observed. To prevent overheating and consequent loss of physical properties the soldering should be done as rapidly as possible.

Machining—Observe the same principles for machining as set forth in the article on "Zinc Die Castings".

Plating, Painting, Lacquering and Enameling—In general, the same methods are used in the finishing of wrought zinc and zinc alloys as are used in finishing zinc base die castings. See the article on "Zinc Die Castings". However, greater caution should be exercised in baked enameling not to exceed temperatures which will impair the mechanical properties. For this reason, air dried finishes are preferable.

Marking—Zinc may be easily marked by the use of commercially prepared metal inks. Such markings are waterproof.

Polishing of Zinc and Its Alloys for Metallographic Examination

By E. A. Anderson* and J. L. Roddat

The preparation of zinc for metallographic examination requires care, not only by reason of the relative softness of the pure metal but because slight distortion will readily cause the formation of mechanical twins. In fact, the presence or absence of twinning may frequently be used as a measure of the care used in preparing the microspecimen. The susceptibility to distortion or mechanical twinning naturally decreases as the hardness of the zinc is increased by alloying or refinement of grain size.

Not infrequently instructions for preparing microsections will be found in which it is directed to continue polishing until scratches from the preceding operation have been removed, although many metallurgists have recognized that this is not sufficient. Experiment has shown¹ that during the normal polishing of cast zinc, distortion may occur to a depth of from 20-100 times as great as the deepest scratch. Since the time required to produce an ideal surface by polishing alone, particularly during the final stages, would be excessive, a saving can be made by etching away some of the metal between polishing steps. This method obviously cannot be used on specimens having relatively large areas of phases having different etching characteristics, since a strong relief once developed cannot be removed on a yielding cloth lap.

Preparation of the surface can be divided into three stages: (1) Rough grinding, preferably on a belt sanding machine; (2) fine grinding by hand on abrasive papers, and (3) polishing on rotating cloth covered discs

For grinding on the sander the following four grades of belts have been found satisfactory: "No-lap" No. 30, 60, 120, and 240. Undue heating of the specimen must be avoided since commercial grades of unalloyed zinc recrystallize at temperatures easily attained at the surface during grinding. Preliminary surfacing on the sander must be carried far enough that distortion from a previous cutting or sawing operation is removed. At least $\frac{1}{16}$ in. should be removed for this purpose.

Hand polishing may be satisfactorily carried out with a series of three or four polishing papers such as "Speed-wet" No. 280, 320, and 400 or Behr-Manning No. 1, 0, 00, and 000. The paper should be backed by a flat surface such as plate glass.

For wet polishing, the use of specially graded abrasives is highly desirable. Methods of preparation and use have been described.¹ Briefly, the method consists of dispersing the commercial abrasive (alumina) in water with a peptizing agent** in a ball mill, then transferring to a beaker. Portions of the supernatant suspension are drawn off at stated intervals so that particles in suspensions for the respective wheels have the following maximum settling rates: No. 1 wheel—1 in. in 20 sec.; No. 2 wheel—1 in. in 3 min.; No. 3 wheel—1 in. in 30 min.; and No. 4 wheel—1 in. in 4 hr. The settling rates from one wheel to the next thus decrease in the approximate ratio of 9-1 while the particle diameter decreases in about the ratio 3-1.

The first two polishing wheels may be covered with white duck. Either a good grade of broadcloth or billiard cloth is suitable for the last two wheels. Finishing on billiard cloth is preferable. The operator's hands and the specimen should be washed with soap and water between operations to avoid the introduction of coarser grit to any wheel.

Using a solution containing 200 g. pure chromic anhydride (CrO_3), 15 g. sodium sulphate (anhydrous), or 34 g. $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$, 1000 cc. water, the following etching schedule has been found satisfactory for removing most of the metal distorted by polishing. As previously noted, this procedure cannot be used where large particles are present of another phase having different etching characteristics.

Etch $3\frac{1}{2}$ minutes after final hand polishing
1½ minutes after No. 1 wheel
30 seconds after No. 2 wheel
10 seconds after No. 3 wheel

After polishing on the fourth wheel the specimen may be etched for microscopic examination. (The etching procedure is described in the following article.)

*Chief, and †Investigator, Metal Section, Research Div., The New Jersey Zinc Co., Palmerton, Pa.

**An agent called "Darvan", used in the rubber trade, has been found better than the sodium silicate first used. Other satisfactory agents are doubtless available.

Mounting Specimens—A brief description of mounting methods may be useful. Rolled metal is commonly polished on a with-grain edge section and may be conveniently mounted in a screw clamp with thin spacers of soft zinc between specimens and heavy strips of zinc outside the assembly. The assembly is tightly clamped to prevent seepage of etching reagents between specimens. The zinc spacers, whose structure is known, serve as a convenient standard of comparison to determine whether or not preparation of the specimens has been properly carried out.

Some of the synthetic resins such as Lucite or Bakelite are convenient mounting media¹ for brittle or irregularly shaped specimens, particularly when microexamination to the very edge is required. With these transparent media, the shape of the specimen can be observed and surface features correlated with microstructure. For many purposes the mounting temperature and time are such that no marked structural changes occur. Convenient presses for the purpose are available on the market.

Etching of Zinc and Zinc Alloys for Metallographic Examination

By E. A. Anderson* and J. L. Rodda†

The most useful etching reagent for zinc is a solution of pure chromic anhydride, CrO_3 (commonly called chromic acid) to which pure sodium sulphate has been added.¹ A pure chromic anhydride solution will not etch zinc. Sulphates and certain other ions appear to act as catalysts, permitting the zinc to be dissolved and the hexavalent chromium reduced. Accurate control of the relative proportions and absolute amounts of chromic anhydride and sulphate is essential to the production of dependable structures and etching rates. Since commercial grades of chromic anhydride frequently contain sulphate as an impurity, it is essential that pure chemicals be used. A grade of chromic acid used for plating has been found satisfactory. Chromic anhydride may be readily tested for the presence of sulphate or other catalyzing ions since a solution of the pure chemical will not etch zinc.

Final polishing of the specimen is best done just before etching. The tip of the finger dipped in alcohol and rubbed over the surface of the specimen will remove any loose abrasive. The specimen should be cleaned by dipping successively in alcohol, ether, alcohol, then in a strong stream of water, excess water shaken off and the specimen etched.

The most useful etching composition for commercial grades of zinc is as follows:

Solution No. 1	Solution No. 2
200 g. pure CrO_3 15 g. Na_2SO_4 or 34 g. $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ 1000 cc. water	200 g. pure CrO_3 1000 cc water

Fifteen seconds immersion will be adequate for examination at 100 dia. At 1000 dia etching for periods longer than one second will frequently cause too much relief.

Certain chromic anhydride-sulphate mixtures, some of which may be produced by diluting the reagent with water, produce a stain film on zinc. This film is soluble in a pure CrO_3 solution which itself will not etch or stain. Use of solution No. 1 or others containing chromic anhydride should therefore be followed immediately by rinsing in solution No. 2. This rinse is followed by thorough washing in a strong stream of water, dipping in alcohol, then ether and drying with a warm blast of clean air.

Etching Copper-Zinc Alloys—For zinc containing copper in solid solution a reduction in the sulphate content of solution No. 1 produces better contrast:

Solution No. 3
200 g. CrO_3 7.5 g. Na_2SO_4 1000 cc. water

Electrolytic etching² in a solution of 200 g. CrO_3 and 1000 cc. water has been found useful in studying other copper-zinc phases, particularly gamma and epsilon. The etching results depend somewhat upon the grain size and distribution of the phases and some experience is required in interpreting the results. In general, however, at current densities greater than 1.5 amperes per sq. in. gamma will be attacked in preference to epsilon; at lower current densities epsilon will be attacked in preference to gamma. Platinum foil or wire may serve as cathode and the current should be on when the specimen is dipped into the solution. Five seconds etching is usually adequate at the higher current densities.

Die Casting Alloys—Structures developed on die casting alloys by solution No. 1 are somewhat unsatisfactory in that the aluminum-rich phase (gamma) is not attacked. G. Edmunds and O. W. Bartholomew³ have found that, in the presence of sodium fluoride, a chromic anhydride solution will etch gamma. By a combination

*Chief and †Investigator, Metal Section, Research Div., The New Jersey Zinc Co., Palmerton, Pa.

of the sulphate and fluoride catalysts the desired result is obtained. The recommended concentrations are:

Solution No. 4
200 g. CrO_3
7 g. Na_2SO_4
2 g. NaF
1000 cc. water

Some slight staining results with alloys containing copper. This may be prevented by transferring the specimen, without washing, to a solution of:

Solution No. 5
50 g. CrO_3
4 g. Na_2SO_4
1000 cc. water

Since this also is an active etching reagent immersion should be brief. Two seconds in No. 4 and one second in No. 5 is usually satisfactory for photographing at 1000X. This treatment should be followed by the usual rinse in solution No. 2 before washing and drying.

Macroetching—Concentrated hydrochloric acid produces good grain contrast on zinc.

Manufacture and Properties of Zinc Die Castings

By E. A. Anderson¹ and Marc Stern²

The Die Casting Process—The die casting process may be defined as the method of making reproducible shapes by casting in a metal die or mold with pressures exceeding those due to gravity. The die casting machine consists of a pot in which to melt the alloy and hold it at the desired casting temperature and a means of forcing the molten metal under high pressure into a die held in a suitable frame which permits it to be opened and closed at will. By suitable use of retractable cores a wide range of shapes may be produced by this method.

Applications—Die castings offer certain distinct economies. Where a number of parts of the same design are required, the use of die castings permits large reductions in machining costs. Parts of intricate ornamental design may be produced at low cost. Several parts may be combined in one die cast, thus reducing assembly costs. When desired, the die castings may be plated, chemically treated, lacquered, enameled, painted, or coated with other organic finishes.

Of the various metals suitable for pressure die castings, zinc has the advantage of low material cost. Furthermore, because of the low melting point of zinc alloys, good die life may be obtained with dies of plain carbon steel and it is not necessary to give the dies special heat treatment.

The following established uses give a general idea of the wide range of suitable applications. In the automotive field body hardware, carburetors, fuel pumps, radiator ornaments, speedometer frames and taxi meter housings and parts are commonly die cast from zinc alloys. Gears for many uses including washing machine and electric hoist gears have proven successful. Refrigerator hardware, door checks, and other interior hardware in the building field; small motor frames, radio chassis and parts in the electrical industry and various housings and brackets, in business equipment offer further examples.

Design—The limitation of size has not been reached. Typewriter frames and radio chassis are fair examples of large castings. The die cast cowl bar weighing 14 lb., with an over-all length of 41 in. and die cast radiator grilles weighing 20-30 lb. represent even larger parts which have come into use. Parts such as the individual units in die cast slide fasteners represent a large field of very small die castings.

The accuracy of dimensions ordinarily attained is ± 0.002 in. per in. of length or fraction thereof up to 3 in. and ± 0.001 in. per in. for each additional inch. Dimensions intercepted by the parting line of the die will show a greater variation, but proper die design will usually avoid having the parting line intercept important dimensions. A draft of 0.001 in. per in. on cores is the minimum desirable allowance.

Alloys—While a number of zinc alloys have been employed in the past, modern die casting practice recognizes only three alloys, all of which have been covered by S.A.E. specifications* and are included in A.S.T.M. specification B86-38T. The compositional limits for these three alloys are given under their specification designations in Table I.

Note: Properties given above are average figures for alloys as die cast. For information on lower limit of properties to be expected in commercial castings, see A.S.T.M. Specification B86-38T.

While the above alloys compare fairly closely in composition, the variations in copper content induce differences in properties which should be taken into consideration in selecting an alloy for a given application. General information concerning these differences is given below.

A.S.T.M. Alloy No. XXIII (S.A.E. No. 903)—This alloy is the most permanent with regard to dimensions and ductility of the commercially used alloys. Its impact strength should not change appreciably under any ordinary service conditions. No dimensional change exceeding 0.001 in. per in. is to be expected in castings of this alloy under normal service conditions. The extent of this dimensional change can be materially reduced by an inexpensive heat treatment.

A.S.T.M. Alloy No. XXI (S.A.E. No. 921)—This alloy has the highest tensile strength and hardness of the commercial zinc alloys. It is inferior to S.A.E. alloys No. 903 and 925 in permanence of dimensions and retention of impact strength at room and elevated temperatures.

A.S.T.M. Alloy No. XXV (S.A.E. No. 925)—This alloy is intermediate between Alloys No. 903 and 921 in tensile strength and hardness. At room temperature, it is equal to Alloy No. 903 in permanence of dimensions and impact strength. At elevated temperatures, it is subject to growth in dimensions and loss in impact strength of lesser magnitude and slower rate than Alloy No. 921. It is somewhat more resistant to surface corrosion than Alloy No. 903. It may be used in virtually any application to which Alloy No. 921 is suited and in place of Alloy No. 903 when additional surface corrosion resistance is required in addition to better permanence than can be obtained with Alloy No. 921.

Steam Test—An exposure in an atmosphere saturated with water vapor at 95°C. for a period of ten days is accepted by the A.S.T.M. as a check on the freedom of the alloy from excessive contents of lead, cadmium, and tin. No undesirable corrosion will take place in this test if the alloys are made to the compositional limits given in Table I.

General—It is generally believed that the physical properties of a cast metal are dependent in a large degree on the casting conditions and the design of the castings. This is particularly true in die castings where there is opportunity for a wide variation in metal flow and chill due to the design, cooling, and operating temperature of the die. The zinc alloys mentioned above are affected by such conditions. For example, the tensile strength may be increased by unusual chilling or lowered through casting in an unusually hot die. The impact strength usually tends to increase with increasing die temperature up to some maximum fixed by the die design, after which a reduction in impact strength may take place with further increases in die temperature.

Die castings are usually of such size and shape that test specimens cannot be machined for actual die cast parts. A standard die for casting tensile and

impact specimens has, therefore, been recommended by Committee B-6 of the A.S.T.M. and widely adopted. The tensile specimen is round with a $\frac{1}{4}$ in. reduced section. The standard unnotched $\frac{1}{4}$ by $\frac{1}{4}$ in. impact specimen is used.

The data on physical properties given in Table II are based on specimens cast in such dies under average conditions. It must be recognized that various sections of commercial castings may differ considerably in properties from these figures due to differences in chill and metal flow.

Fig. 1—Cutting angles for zinc.

Machining—A primary machining requirement is the maintenance of a keen, smooth cutting edge. High speed steels are usually satisfactory, but for exacting dimensional requirements special cutting tools, such as tungsten carbide, are effective. Cutting angles for machining zinc are given in Fig. 1.

Milling cutters, end mills, reamers, and similar tools produce the best results when they are of coarse tooth spiral or helical design with appreciable top and side rake. Two-fluted spiral taps with ground and relieved threads which provide ample chip clearance and rapid chip removal have been found satisfactory.

The same principle applies to drills where two-fluted drills, with spiral angles about double the usual 24° , are satisfactory.

The included angle of the cutting edges may be advantageously reduced. The clearance angle may be increased to 15° at the periphery of the drill and gradually increased still further as the drill point is approached. Beveling off the end of the flute back of each cutting edge provides more chip clearance for rapid work.

Finishing—Electroplated finishes are largely employed in finishing zinc base die castings. The degree of protection against various exposure conditions which can be obtained by plating is dependent in the case of zinc die castings as in the case of other metals upon the quality and weight of plating. In present practice, coatings in the order of 0.001 in. in thickness are considered necessary for satisfactory protection under conditions of outdoor exposure.

While nickel is widely used as the first coat under chromium finish coatings, it is impossible to safely produce heavy coatings with a single deposit of nickel. Any warm nickel solution which contains no sodium sulphate and operates above pH 4.8 may be used in producing heavy deposits on zinc, provided a protective strike coating is first applied. This strike coating may be either copper or nickel. For copper plating a cyanide solution containing Rochelle salt is widely used. A solution suitable for nickel strike plating is as follows:

Single nickel salts—10 oz. per gal. (75 g. per l.)
 Anhydrous sodium sulphate*—15 oz. per gal. (112 g. per l.)
 Ammonium chloride—2 oz. per gal. (15 g. per l.)
 Boric acid—2 oz. per gal. (15 g. per l.)
 Temperature—Room temperature.
 Current density—8 to 20 amperes per sq. ft.

After strike plating for 5 min. in the above solution, the work is rinsed in cold water and transferred to a warm nickel solution for completion of the plating. Work which has received a copper strike is rinsed thoroughly, dipped briefly in a 5-20% sulphuric acid solution, again rinsed, and placed in the warm nickel solution.

The preparation of the castings for plating does not present any unusual problems. It is best to avoid deep grinding which may cut through the surface layer which offers the best surface for plating. Any suitable proprietary cleaner may be used. The following solution used as an electrocleaner at $170-180^\circ\text{C}$. has operated successfully:

6 oz. of trisodium phosphate per gal. of water (45 g. per liter).

Care should be taken to avoid overcleaning and the work should be given a brief dip in 5% hydrochloric or 5% sulphuric acid to neutralize alkaline films before plating.

*Use 20 oz. per gal. if hydrous sodium sulphate is used.

Organic finishes will normally require chemical pretreatment to insure satisfactory adherence. Of those tested, the phosphate type of pretreatment appears to be the most effective. Lacquers may be used effectively but better adherence qualities are obtainable with baking finishes. Baking finishes are available which may be applied at baking temperatures as low as 250°F. The use of higher temperatures is possible under some conditions, although the possible effect of the temperature on the physical properties should be taken into consideration. With excessive temperatures, there is danger of blisters forming as the result of the expansion of any air bubbles near the surface of the casting.

specifications.....	512-515
shear blades.....	1033, 1034
spark testing.....	775
tool steel, trade names.....	13-37
welding methods.....	451, 483
altering elements in steel, distribution.....	430
at elevated temperatures.....	581
at high strength, low alloy steels.....	479-483

metallographic effects.....	821-824
nonmetallic inclusions.....	823
purpose of additions.....	819
relation of elements to carbon.....	825
to hardenability.....	825
trends of influence.....	827
Ainige (iron-nickel-aluminum magnet).....	808
Aluminizing (colorizing).....	1003-1004
Aluminum, cold forming.....	1300, 1306
commercially pure, wrought, corrosion resistance.....	1246
distance.....	1246
mechanical properties.....	1246
uses.....	1247
welding.....	1246
control of grain size by.....	610
for deoxidizing.....	890
determination of, in steel.....	954
electrical properties.....	1246
etching for metallographic examination.....	1290-1294
extraction methods for production of.....	1318
fluidity of.....	101, 1242
hardeners for.....	1298-1297
high purity, physical constants.....	1246-1245
hot forming.....	1310
industry.....	1319-1320
ores of.....	1310
products.....	1310
refining of.....	1313
uses.....	1319
machining of.....	1315-1320
magnetic properties.....	1246
molten, measuring temperature.....	1298-1291
optical properties.....	1246
ores of.....	1310
physical constants.....	1246-1245
physical properties.....	1246-1245
polishing for metallographic examination.....	1298-1299
products and production.....	1310
recrystallization temperature.....	300
refining.....	1310
spinning.....	1321-1322
in steel, control of grain size.....	510
uses.....	906, 1310
in zinc die castings.....	1770
Aluminum alloy die castings, anodic treatment.....	1306
finishing operations.....	1306, 1307
machining.....	1306
plating.....	1307
Aluminum alloys, cold working.....	1308, 1309
compositions.....	1309
constituents in, identification.....	1304
density.....	83
die castings.....	1302-1307
etching characteristics.....	1290-1294
extrusion.....	881
hardeners for.....	1298-1297
hot working.....	1309, 1310
machining.....	1315-1320
macroscopic examination.....	1298, 1299
microscopic examination.....	1290-1294
polishing for metallographic examination.....	1298, 1299
spinning.....	1321, 1322
welding.....	1306
wrought.....	1311-1314
Aluminum bronze, cast, composition.....	1426
manufacture.....	1426
properties.....	1426
specifications.....	1426
uses.....	1426
cold working.....	1426, 1428
hot working.....	1430, 1431
wrought, composition.....	1426, 1428
manufacture.....	1426
properties.....	1426, 1428
uses.....	1426
Aluminum-chromium alloys, composition.....	1422

- Aluminum-copper alloys, aluminum-rich con-
 stitution 1222, 1223
 bronze, aluminum 1205, 1225
 casting alloys, casting properties 1248
 heat treatment 1248
 mechanical properties 1248
 casting alloys (4% copper) 1252, 1253
 heat treatment and properties 1252, 1253
 specifications 1252
 uses 1253
 casting alloys (8% copper), composition 1250
 properties 1251
 specifications and uses 1250
 copper-rich, constitution 1242, 1243
 for die castings 1203
 physical properties 1246, 1251, 1252
 wrought alloys, composition 1248, 1249
 Aluminum-copper hardeners for aluminum 1295
 Aluminum-copper-iron-magnesium alloy,
 cast 1268, 1269
 mechanical properties 1268
 physical properties 1268
 uses 1268, 1269
 Aluminum-copper-magnesium-manganese
 alloy (17S or Duralumin), compo-
 sition 1270
 corrosion resistance 126, 1270, 1271
 heat treatment 1271
 mechanical properties 1270
 temper designation 1270
 uses 1270, 1271
 welding 1271
 workability 1271
 Aluminum-copper-magnesium (1.5%)-manga-
 nese alloy (24S and Alclad),
 wrought 1272, 1273
 composition 1272
 corrosion resistance 1272
 heat treatment, solution 1273
 temper designation 1272
 uses 1273
 welding 1273
 workability 1272
 Aluminum-copper-manganese alloy, cold
 forming 1309
 Aluminum-copper-manganese-magnesium
 alloy, cold forming 1309
 Aluminum-copper-nickel-magnesium alloy,
 cast, composition 1274
 mechanical properties 1274, 1275
 physical properties 1274
 specifications 1274
 uses 1274
 Aluminum-copper-zinc hardeners for
 aluminum 1296
 Aluminum impregnation 1082
 Aluminum industry, details of 1218-1220
 Aluminum-iron alloys, constitution 363-365, 1224-1225
 calorizing process 1082, 1083
 Aluminum-iron hardeners for aluminum 1297
 Aluminum-iron-nickel alloys, constitution 416, 417
 Aluminum-magnesium alloys, see also mag-
 nesium-aluminum alloys
 cast (4% Mg), physical properties 1259
 specifications 1259
 cast (10% Mg), physical properties 1258
 specifications 1258
 uses 1258
 casting alloys, characteristics 1254
 coefficient of expansion 1256
 constitution 1256, 1257, 1258, 1259
 corrosion resistance 1257
 density 1256
 electrical and thermal conductivity 1256
 endurance limit 1257, 1258, 1259
 tensile properties 1256, 1257
 working characteristics 1255
 wrought, properties 1254
 Aluminum-magnesium-chromium alloys (34S),
 annealing 1267
 composition 1267
 corrosion resistance 1267
 mechanical properties 1267
 physical properties 1267
 uses 1267
 welding 1267
 workability 1267
 Aluminum-magnesium-silicide,
 constitution 1235, 1236
 Aluminum-magnesium-silicon alloys,
 constitution 1239, 1240
 wrought, annealing 1276
 composition 1276, 1280, 1284
 corrosion resistance 1276
 heat treatment 1276
 mechanical properties 1276
 physical properties 1276
 uses 1276
 welding 1276
 workability 1276
 Aluminum-magnesium-zinc alloys,
 constitution 1237, 1238, 1239
 Aluminum-manganese alloys,
 constitution 1228, 1229
 wrought, annealing 1260
 composition 1260
 corrosion resistance 1260
 mechanical properties 1260
 temper designation 1260
 uses 1260
 welding 1260
 workability 1260
 Aluminum-manganese hardeners
 for aluminum 1295
 Aluminum-manganese-magnesium alloy,
 wrought, annealing 1260
 composition 1260
 corrosion resistance 1260
 mechanical properties 1260
 temper designation 1260
 welding 1260
 workability 1260
 Aluminum-nickel alloys,
 constitution 1230, 1621, 162
 Aluminum-nickel hardeners for aluminum 129
 Aluminum-silicon alloy, cast, electric
 properties 1262
 mechanical properties 1263
 thermal conductivity 1263
 casting alloy (5% Si), mechanical
 properties 1266, 1305
 physical properties 1266, 1305
 specifications 1266
 casting alloy (13% Si), mechanical
 properties 1265
 modified, properties and uses 1265
 physical properties 1265
 specifications 1265
 uses 1265
 casting properties 1263, 1264
 constitution 1231, 1232
 corrosion resistance 1263
 density 1261
 die casting alloys 1264
 growth of 1261
 hardener for aluminum 1295
 high purity, electrical resistance 1262
 properties 1261-1264
 welding rod 1264
 Aluminum-silicon-copper alloys,
 die castings 1304, 1305
 Aluminum-silicon-copper-magnesium casting
 alloys, heat treatments 1278, 1279
 properties 1278
 specifications 1279
 uses 1278
 Aluminum-silicon-magnesium casting alloy,
 mechanical properties 1280
 physical properties 1280
 specifications 1280
 uses 1280, 1281
 wrought, annealing 1285
 composition 1284
 corrosion resistance 1284
 formability 1284, 1285
 heat treatment 1284
 mechanical properties 1284
 physical properties 1284
 temper designation 1284
 welding 1284
